Abstract

Growth and body height have always been interesting topics in the public opinion. Particularly the stupendous increase of some 15 to 19 cm in final adult height during the last 150 years in most European countries (the “secular trend”), the concomitant changes in body and head proportions, the tendency towards early onset of sexual maturation, the changes in the age when final height is being reached, and the very recent trend in body mass index have generated much scientific literature. The marked plasticity of growth in height and weight over time causes problems. Child growth references differ between nations, they tend to run out of date, and raise a number of questions in regard to fitting methodology, effects caused by selective drop-out etc. New findings contradict common beliefs about the primary importance of nutritional and health related factors on secular changes in growth. There appears to be a broad age span from mid-childhood to early adolescence that is characterised by a peculiar insusceptibility. Environmental factors that are known to influence growth during this age span appear to have only little or not impact on final height. Major re-arrangements in height occur at an age when puberty has almost been finished and final height has almost been reached implying that factors which drive the secular trend in height are limited to early childhood and late adolescents.

Position statement

The so-called secular trend in human growth is not a consistent and homogeneous event uniformly occurring in height, weight, body shape, various circumferences, and other anthropometric parameters. The trend exhibited distinctly dissimilar dynamics in the various parameters, during the economic transition of the past 150 years. Whereas the trend in height has come to a halt within most Western countries, differential trends are to be observed in weight and in various circumferences. The authors provide new evidence suggesting that not only the parameters, but also the age groups differ in susceptibility, with infancy and early childhood, and late adolescence being most vulnerable to those socio-economic and environmental factors that drive the secular trend.
The symposium started with a short outlook on the recent direction of the secular trend in height by Elena Godina (2009). The secular trend occurs early in life and becomes greater through puberty. Children on average increased in height by about 1 to 2 cm per decade at age 5 to 7, and by 2 to 3 cm per decade at age 10 to 14. Adults show 1 cm increase in height per decade. Apart from increases in body height, the trend includes changes in body and head proportions, a tendency towards early onset of sexual maturation, and changes in the age when final height is being reached. Whereas secular increases in stature have slowed down or completely stopped there is an ongoing increase in body fatness in many European countries. However, in various parts of Eastern Europe, recent evidence was presented for an inverse trend in young women towards a increase in slenderness. Whereas body height increased in 15 year old Moscow women, a decrease in weight by 2 kg, a decrease in chest circumference by 3 cm since 1975, and a decrease in pelvic breadth were noted. In young Saratov women BMI decreased from 21 kg/m² to 20 kg/m².

Frank Rühli presented collaborative work (K. Staub and C. Pfister, Institute of History University of Bern; U. Woitek, Institute for Empirical Research in Economics; University of Zurich) on 19 year-old Swiss male conscript data (N = ca. 23,000, Staub et al., Eur J Clin Nutr, in press) from various cantons from 1875-9 till 2005-6. Mean BMI of 19-year old men in Switzerland increased between the 1870s and the 1930s by 0.80 kg/m² and between the 1930s and 2005 by 1.45 kg/m². The modern BMI sample is much more right-skewed and the SD is generally larger. The obesity prevalence (according to WHO classification) has increased by a factor of more than 100 since the late 19th century. The trend towards increase in weight rather than height continues even in the most modern decade. Currently, more than 20% of 19-year old Swiss men have a BMI above 25 kg/m². Unskilled workers are much heavier than students, in contrast to the 19th century, when the prevalence of overweight was the opposite.

Pavel Blaha evaluated parental data (324,155 fathers and 334,043 mothers) obtained from the Nationwide Anthropological Surveys of Children and Adolescents, and discussed trends in height of the Czech population during the last century (fathers born between 1870 and 1984,
mothers born between 1880 and 1984). Height of fathers increased from 167.4 to 180.6 cm, height of mothers increased from 158.7 cm to 167.6 cm (Figure 1a/b). According to physical stress, body height differed by some 2 cm in fathers, and by 1.7 cm in mothers in 1951. The differences in body height between fathers and mothers changed. Between 1880 and 1960, the differences increased up to 13.7 cm, and thereafter dropped to 12.8 cm in 1984. Since 1951 the rate of obese fathers increased, whereas the rate of obese mothers declined. In the surveys 1981 and 2001 the prevalence of obesity increased with age.

Jesper L. Boldsen concentrated on formulating relevant research hypotheses and the feasibility of establishing truly longitudinal studies of growth, health and mortality in past populations. The vast majority of the skeleton undergoes constant remodeling through the action of osteoclasts and osteoblasts. This remodeling takes place with different speed in different parts of the skeleton. As a rule of thumb trabecular bone tissue remodels in t quicker pace than compact bone tissue does. In mature individuals it can be assumed that trabecular bone chemically reflects the individual some five years prior to death, whereas compact bone tissue is generally ten year old at death. However, certain parts of the human hard tissues are chemically and morphologically fixed in different time of childhood and adolescence times. The trace element profile in a given bone or tooth sample carries a signature of the food and environmental exposure of the individual at the age when it was formed and fixed. Permanent teeth mineralize from just before birth (the tip of the crown of central incisors and first molars) to adulthood (the root tip of the third molar. To my knowledge Pars petrosa (the bone surrounding the inner ear) is the only bone that does not remodel after it is formed in an age of two years. These facts facilitate the writing of an individual chemical life history of a human being who lived many hundred years ago. The research potential is tremendous – not only for historical studies of health but also for finding causal associations. The discovery of this research possibility is relatively new so no published results have yet been produces, but the research catalogue is already long: The age of weaning in children who survived to adulthood; the effect of age of weaning on adult immunocompetence (as measured by expression of leprosy); childhood nutrition and adult stature; medieval nutrition history; etc.

Stef van Buuren analyzed why WHO child growth standards of weight for age differed from all national curves, and discussed the effects of fitting methodology and selective drop-out.
Children of the WHO group are significantly heavier during the month 1-6, the gap widens between months 1-3 and closes between months 3-6. Thereafter the WHO group is lighter. Whereas curve fitting methodology did not cause these differences, selective drop-out proved to be a major source of error.

The WHO sample is highly selected for factors likely to promote growth in breastfed infants and less than 10% of those initially surveyed were included in the final study (Binns and Lee 2006). Since most mothers and professionals are concerned about the growth of their infants particularly for the first 6 months, they are likely to introduce supplementary foods and early abstain from breastfeeding on the basis of perceived slower growth.

With the example of the Dutch SMOCC study, consisting of 2151 infants born between 1989 and 1990, longitudinally investigated at 0, 1, 2, 3, 6, 9, and 12 months of age, van Buuren showed that up to month 1 exclusively breastfed (EBF) infants are heavier at birth. Apparent higher than average growth of EBF infants during the months 1-2 is primarily attributable to selective dropout. Between months 2 and 6, light non-EBF infants gain more weight than light EBF infants. Selective drop-out continues to operate even thereafter. Thus, the decision to abort EBF strongly depends on infant weight, and may explain why the WHO references show a significant upwards bias especially during the first 3 months. This is a serious issue as the new WHO charts have the potential to undermine breastfeeding during the first 6 months (Van Buuren, 2010).

Matthew McIntyre reviewed current evidence that the association between age at pubertal onset and final height has reversed historically from negative to positive (do Lago, et al, 2007; Onland-Moret, et al. 2005). This finding is interpreted as resulting from the approach toward maximum childhood growth rates in all social classes which eliminates the spurious negative association between age at pubertal onset and final height (via the common cause of prepubertal growth). Remaining variation in final height is more strongly influenced by age at puberty, variation in which is now determined by genetic and early developmental factors and intergenerational factors (Figure 2).

Michael Hermanussen and Christian Aßmann re-investigated 5 large national longitudinal growth studies consisting of a historically mixed sample of altogether 735 children and adolescents (350 boys, 385 girls) from Berkeley, Prague, Zurich, Paris and Lublin. The
participants were born between 1928 and 1965, were measured at regular annual intervals between the age of 1 and 18 years (boys) and 1 and 17 years (girls), and were brought up under very different historical, socio-economic and political circumstances. We assume that the heterogeneity of the environmental circumstances under which these children grew up, should be mirrored in their growth.

We transformed all height measurements into height SD scores (hSDS) and investigated changes in hSDS. We correlated hSDS between subsequent years, we analyzed the correlation of hSDS at each age with final hSDS, and we determined R² and 1-R², and thereafter converted 1-R² into cm². 1-R² was called “free variance”. High 1-R² indicates vivid hSDS change; low 1-R² indicates stabile tracking in hSDS. The changes of 1-R² over the age range mirror the changes in susceptibility to nutritional, health related, socio-economic and political circumstances that had influenced growth between birth and maturity.

Figure 3 illustrates the changes of “free variance” over the age range. Significant peaks in susceptibility occurred early in life and late in adolescence at the age of 16 years in boys, and at an age of 14 years in the girls, i.e. some 2 years after peak height velocity. The pattern appears similar in both genders and in all 5 growth studies.

Quite in contrast to common beliefs, there appears to be a broad intermittent age span of insusceptibility to environmental influences on growth. Influences on growth during this age span appear to have little or not impact on final height. The fact that major re-arrangements in height position occur at an age when puberty has almost been finished and final height has almost been reached, implies that factors which drive the secular trend in height are limited to early childhood and late adolescents.

Arnab Ghosh provided an overview on growth and development in children and adolescents of Asian Indian origin from West Bengal, India. Malnutrition is more common in India than in Sub-Saharan Africa using WHO cut-offs. One in every three malnourished children in the world lives in India. Close to 50% of the deaths under 5 years of age occur during the first months of life. The majority of these children die at home although they have contacted health personnel at least once. But even though the majority of the children still remain undernourished, the modern Indian prosperity creates a paradox. The recent economic transition with increasing wealth has resulted in an increase in overweight and obesity, hypertension, diabetes and cardiovascular disease.
Gian Franco de Stefano described growth in a sample of 3547 individuals (1781 males and 1766 females, aged 1 to 18 years) of a population of African Ancestry settled in Esmeraldas, the main urban area of North Western Ecuador. Percentile lines were estimated using a combination of modelling Preece-Baines model 1 (PB1) to the mean values and LMS to estimate the percentile distribution. The goodness of fit was estimated by comparing the number of measurements between the percentile bands with expected number of observation, and appeared satisfactory. The curves were then compared with the 2000 international reference standard proposed by the NCHS (Kuczmarsky et al 2000). The fitted PB1 model estimated the age at maximum height increment in males at 13.29 years and in females at 10.95 years.

Valentin D. Sonkin presented data on the nutritional status of Russian school children based on questionnaires of 70,000 pupils of the 1-2 and the 10-11 forms of 56 regions of the Russian Federation (Bezroukich 2004). Nearly 20% of Russian school children are not adequately nourished while near 2.5% have insufficiently ration. The food quality partially depended on family economics, but most children and their parents do not know how to organize regular nutritional regimen. School nourishment is often poor in quality and organization. Meat or fish, and potatoes were consumed daily by 50-60%, milk, cheese and eggs by 70-80% of children of all ages. Bread and wheat products were daily consumed by about 40% of the children, whereas 30% of the first form pupils, but less than 10% of the 10th form pupils consumed fruit or fruit juice on a daily basis. 30% of the first and the 10th form pupils had three meals per day, 30% of the first, but only 10% of the 10th form pupils had more than three meals. 50% of the 10th form pupils had meals at irregular intervals. Almost 40 of this age group had no lunch. The effects of malnutrition are usually evident in physical performance, rate of sickness and the number of accident. It was amazing to find that in contrast to common expectation (Godina and Miklashevskaya, 1989, Lisovskii et al. 2004), nutritional quality appeared to have no impact on body height and weight.

Jesus A.F. Tresguerres presented new data on the anti-inflammatory action of growth hormone (GH) and melatonin on the cardiovascular system. Many age-related alterations of the cardiovascular system are due to oxidative stress or inflammation. GH, melatonin and sex hormones are reduced with age. Replacement therapy with growth hormone or melatonin are
able to revert at least partially oxidative stress and inflammation thus, reducing the age related alterations. Tresguerres discussed the role of growth factor withdrawal during the process of natural ageing on apoptotic pathways with particular emphasis on the mitochondrial and cytosol cytochrome c fraction, on immunoreactive TNF, IL-6, iNOS, BAX, Bcl2, NFkB2, and their importance in the pathway of melatonin action.

Christof Meigen provided evidence in 471,477 single height measurements of children and adolescents aged 0-18 years, that the Zodiac sign (month of birth) associates with body height. Due to legal cut-off ages, children born in May enter school at an age of 6 years, whereas children born in July enter school one year later. Thus, the Zodiac sign influences a child’s age among his/her class mates. Figure 4 illustrates that the month of birth effect rapidly increases at the age of 6 years in both genders, tends to decline during prepuberty, and reaches a new maxima late in adolescents explaining some 0.1 percent of height variation. Due to large number, the effect of the Zodiac sign on height appears significant in late adolescence. Yet, its clinical relevance needs to be elucidated.

Christiane Scheffler presented new 2009 data on body composition of 6 – 12 year old children (680 boys, and 592 girls) from Brandenburg (Germany), and compared them with a 1999 sample from the same geographic regions consisting of 1398 boys and 1462 girls, aged 6 – 12 years (Schilitz and Greil 2000, Greil and Schilitz 2000). Between 1999 and 2009, weight and BMI, and the percentage of body fat had increased. Today’s children are smaller, and their skeleton robustness had significantly decreased. Currently it remains to be elucidated wither this novel trend is caused by decelerating developmental tempo, or whether there is a truly new negative trend in height in modern 6-12 year old children. This trend maybe is caused by an decrease in physical activity (Scheffler et al. 2007).

Cherie Geiger and Leslie Sue Lieberman reported on environmental toxicants with particular focus on polychlorinated biphenyls (PCB) and lead, their remediation and their influence on growth variation, height and the secular trend. PCBs possess high chemical stability, low flammability and low electrical conductivity. They are used in a variety of industrial applications. Through 1976, 1.3 billion pounds were manufactured (1.25 billion pounds in the
PCB’s are considered persistent, ubiquitous pollutants, they are found in nearly all plant/animal life, their concentrations tend to increase travelling up the food chain. Research in remediation technologies for both PCBs and lead in the environment has improved in recent years but still focuses on high-concentration contaminated areas (DeVor, et al, 2008; Runkel, et al, 2009; Friesl-Hanl, et al. 2009). PCB’s are (anti) estrogen-like endocrine disrupting chemicals interfering with synthesis, metabolism, binding and cellular responses of natural estrogens. Some congeners advance and/some delay puberty (Chakraborty and Chakraborty, 2009). They may interfere with thyroid function elevate anti-thyroid peroxidase antibodies and are related to neurobehavioral problems associated with alterations in Ca channel ryanodine receptors and untruncated dendrite growth (Yang et al, 2008).

Major sources of lead are paint, gasoline, water distribution systems, food, and lead used in hobby activities. Though between 1976 and 1990, lead used in gasoline declined by 99.8% in the United States, still much lead contamination is found. Paint with high lead content is estimated to be in 74 percent of all housing built before 1980, and causes as much as 90% of childhood lead poisoning. Maternal and infant prenatal and postnatal blood lead concentrations are associated with disruption of thyroid function, physical growth stunting, cognitive development and immune system impairment. Linear growth is impaired due to chondrocyte hyperplasia, hypertrophy and interrupted calcification thereby, stunting long bone growth. Reduced osteoblast proliferation and migration is a secondary cause of stunting (Ignasiak et al, 2006). Body lead burden and child growth are significantly inversely related in some, but not all studies; and therefore, the issue of whether the adverse effects of lead are a threshold effect or dose response phenomenon are not resolved (Little et al, 2009).

There are a number of issues that the confound studies of environmental toxicants on human health, growth and development. These include: identifying the sources and timing of exposures, measuring chronic and acute exposures, selection of tissues and reference values, interactions with other environmental and biological variables and the small sample sizes of varying chronological ages and developmental stages (Schell, Gallo, Ravenscroft, 2009). The paucity of good studies and increasing concern about environmental health issues prompted the National Institute of Child Health and Human Development (National Institutes of Health) to initiate the National Children’s Health Study in 1999. This study examines the effects of environmental influences on the health and development of 100,000 children across the US.
United States, following them from before birth until age 21 years (http://www.nationalchildrensstudy.gov). This is a definitive study of unprecedented scope.
