Psoriasis is a chronic inflammatory disease affecting up to 2% of the global population. While the pathogenesis of psoriasis is not fully understood, yet, increasing body of evidence suggests a genetic predisposition and an environmental component. The most common manifestations are papulosquamous plaques symmetrically located on extensor surfaces of the joints. While most psoriasis patients report that their skin manifestations have a negative impact on their quality of life, psoriasis is not just a skin disease. Indeed, similar to other systemic inflammatory diseases, inflammation is widespread in psoriasis and arthritis is found in up to one quarter of patients that precedes the disease in 10% of the patients.\(^1\) Importantly, life expectancy is reduced in psoriasis by up to 4 years, which has been attributed to a higher incidence of cardiovascular diseases.\(^2\)

In this issue of the journal, Ahlehoff et al report an association of psoriasis with increased risk of atrial fibrillation and ischemic stroke. The authors analyzed 36'765 patients with mild and 2793 patients with severe psoriasis and compared these with over 4 million individuals of a nationwide Danish registry. Indeed, several important pieces of information can be retrieved from this study. First, the study is a further epidemiological milestone in delineating the associated risk of not only severe but also mild psoriasis with vascular disease. Secondly, the study demonstrates a considerably elevated risk not only for cardiovascular disease per se but for atrial fibrillation and ischemic stroke, in particular. While confounding and misclassification might be a concern in any registry based
study, the authors provide further evidence that psoriasis is not just a skin, but indeed a systemic disease. Notwithstanding patients with psoriasis have a high prevalence of cardiovascular risk factors, such as smoking, dyslipidemia, hypertension, obesity and insulin-resistance, systemic inflammation beyond the skin may provide an explanation for the increased cardiovascular risk observed in psoriasis.¹

Psoriasis shares striking similarities with other systemic inflammatory diseases, such as rheumatoid arthritis and atherosclerosis. Intriguingly, the typical histologic features of the psoriatic plaque with dermal inflammation and leukocyte infiltration are similar to the atherosclerotic plaque (Figure 1).³ In atherosclerosis, psoriasis and rheumatoid arthritis, the activation of the innate immune system starts an inflammatory cascade, particularly involving T helper 1, T helper 17 and regulatory T-cells and downstream expression of cytokines.⁴ Inflammation induced by psoriasis also impacts on insulin resistance both of which are important surrogates for early, subclinical atherosclerosis and prognostic markers for cardiovascular disease and may alter the function of endothelial cells, resulting in a propensity towards endothelial dysfunction and early structural changes of the arterial wall. Indeed, several studies demonstrated impaired endothelial function and increased intima-media thickness in patients with psoriasis.⁵

Does atrial fibrillation fit into the story of psoriasis being a systemic inflammatory disease? Recent studies established chronic inflammation as a risk factor for atrial fibrillation⁶ which is of particular clinical relevance as inflammation
might contribute to the prothrombotic state of atrial fibrillation and its clinical sequelae. Remarkably, Ahlehoff and colleagues also reported an increased rate of venous thromboembolism in their cohort of psoriasis patients.

Since the paper by Ahlehoff adds to the increasing evidence of increased cardiovascular risk in patients with chronic inflammatory diseases, patients with psoriasis should be informed by their treating physician that they may have an increased chance of cardiovascular disease. This, however, begs two important questions with regard to potential therapeutical implications. First, should we be more aggressive in treating risk factors in these patients, and secondly should we specifically target inflammation? Risk factors should be assessed, and lifestyle interventions and pharmaceuticals prescribed as appropriate. Since LDL levels are elevated and correlate with the severity of psoriasis, initiation of statins should be considered and goals for LDL cholesterol levels be based on cardiovascular risk assessment. Close monitoring of liver function and creatinkinase are mandatory, especially in patients receiving immunosuppressive drugs to avoid liver toxicity and rhabdomyolysis. In addition to their well-documented LDL lowering effects, statins exert additional pleiotropic, anti-inflammatory effects, that may contribute to the improvement of endothelial function demonstrated in patients with atherosclerotic vascular disease as well as in patients with rheumatoid arthritis, especially in those with high levels of systemic inflammation. Intriguingly, cardiovascular treatment aimed at preventing and treating atherosclerosis may also be beneficial in reducing
psoriasis disease severity, as statins reduced psoriatic cutaneous plaque activity.\textsuperscript{12} While many patients with psoriasis present with low HDL levels,\textsuperscript{10} there is currently no indication for niacin and fibrates in patients with psoriasis, especially as both of these drugs are associated with a worrisome higher rate of side effects in patients with systemic inflammatory diseases.

In patients with psoriasis and elevated blood pressure, lifestyle changes should be implemented and calcium antagonists, thiazide diuretics and angiotensin converting enzyme inhibitors (ACE-I) may represent the drugs of first choice. ACE-I also exert anti-inflammatory and antioxidative effects and are similarly effective as statins in improving endothelial dysfunction in rheumatoid arthritis.\textsuperscript{13} In contrast, beta-blockers should be prescribed with caution since they are reported to be associated with the exacerbation of psoriasis. While patients with systemic inflammatory disease have not been included in previous cardiovascular outcome trials, aggressive management of conventional cardiovascular risk factors seems prudent in patients with systemic inflammatory disease who show an increased cardiovascular risk similar to that of diabetics.

The benefit of any specific antiinflammatory therapy, however, remains still to be established. In fact, antiinflammatory drugs might be double-edged, especially non-steroidal anti-inflammatory drugs (NSAIDs) that are commonly used in psoriasis arthritis. Their antiinflammatory and analgesic effects notwithstanding, NSAIDs and selective COX-2 inhibitors, increase blood pressure and cardiovascular risk.\textsuperscript{14} Their blood pressure rising effects must not be underestimated, notably an effect even observed with paracetamol
(acetaminophen), as hypertension has well known effects on the incidence of atrial fibrillation and stroke. As such, we are facing a dilemma when trying to specifically target systemic inflammation. While antiinflammatory drugs hold the potential of providing benefit through targeting inflammation, they may exert potent off-target effects. This is even more problematic in severely symptomatic patients receiving immunosuppressive drugs, since corticosteroids and cyclosporine not only increase blood pressure, but also worsen dyslipidemia, all further enhancing cardio- and cerebrovascular risk. This true equipoise is further documented by observational studies demonstrating beneficial cardiovascular effects of low-dose methotrexate. This set the stage for cardiovascular outcome trials with methothrexate currently under-way and will provide the answer whether this anti-inflammatory and immunmodulatory drug will improve survival in high-risk cardiovascular patients.

Novel biologics, such as TNF-alpha inhibitors have been proven highly effective in the treatment of psoriasis and other inflammatory diseases. First evidence whether potent antiinflammatory treatment would not only alleviate symptoms but also impact on cardiovascular surrogates, came from studies demonstrating that TNF-alpha suppression improved vascular function in patients with rheumatoid arthritis and may have beneficial impact on carotid intima media thickness in psoriasis. Whether TNF-alpha blockade might beneficially impact on cardiovascular morbidity and mortality in patients at increased risk because of systemic inflammatory disease, however, remains still to be determined.
Novel targeted biologic agents for the treatment of psoriasis are on the horizon, among them several monoclonal anti-Interleukin antibodies like briakinumab, ustekinumab and tocilizumab. Due to the sheared immunological mechanisms between psoriasis (and other inflammatory diseases) and atherosclerosis, they may hold the potential for the treatment of both diseases, but randomized clinical trials addressing efficacy and safety are yet to be performed.

Taken together, the present study adds to the increasing body of evidence of an association between psoriasis and cardio- and cerebrovascular diseases. Although inflammation in these patients may not be limited to skin and joints, but indeed be widespread throughout the vascular tree, there is an unmet need for further research and outcome trials in this field. As a consequence for clinicians, psoriasis patients, particularly those with moderate or severe forms should not only be treated for skin lesions and arthritis but also rigorously screened for vascular risk factors, especially as these patients are often young and could therefore profit most when preventive strategies are implemented early. In the future, large-scale randomized clinical trial studies are needed to define whether patients with systemic inflammatory diseases as psoriasis will benefit from aggressive risk factor control and/or anti-inflammatory treatment.

This would be of particular interest for our specialty, as the benefit of a specific antiinflammatory treatment has yet to be established in the systemic inflammatory disease we care about the most, atherosclerosis.
