Measurements of $W\gamma$ and $Z\gamma$ production in $pp$ collisions at $\sqrt{s} = 7$ TeV with the ATLAS detector at the LHC

ATLAS Collaboration; Abbott, B; Aad, G; Abajyan, T; Canelli, F; et al

Abstract: The integrated and differential fiducial cross sections for the production of a $W$ or $Z$ boson in association with a high-energy photon are measured using $pp$ collisions at $\sqrt{s} = 7$ TeV. The analyses use a data sample with an integrated luminosity of $4.6 fb^{-1}$ collected by the ATLAS detector during the 2011 LHC data-taking period. Events are selected using leptonic decays of the $W$ and $Z$ bosons [$W(e\nu, \mu\nu)$ and $Z(e^+e^-, \mu^+\mu^-, \nu\bar{\nu})$] with the requirement of an associated isolated photon. The data are used to test the electroweak sector of the Standard Model and search for evidence for new phenomena. The measurements are used to probe the anomalous $WW\gamma$, $ZZ\gamma$ and $Z\gamma\gamma$ triple-gauge-boson couplings and to search for the production of vector resonances decaying to $Z\gamma$ and $W\gamma$. No deviations from Standard Model predictions are observed and limits are placed on anomalous triple-gauge-boson couplings and on the production of new vector meson resonances.

Measurements of $W\gamma$ and $Z\gamma$ production in $pp$ collisions at $\sqrt{s} = 7$ TeV with the ATLAS detector at the LHC

The ATLAS Collaboration

Abstract

The integrated and differential fiducial cross sections for the production of a $W$ or $Z$ boson in association with a high-energy photon are measured using $pp$ collisions at $\sqrt{s} = 7$ TeV. The analyses use a data sample with an integrated luminosity of 4.6 fb$^{-1}$ collected by the ATLAS detector during the 2011 LHC data-taking period. Events are selected using leptonic decays of the $W$ and $Z$ bosons [$W(e\nu, \mu\nu)$ and $Z(e^+e^-, \mu^+\mu^-, \nu\bar{\nu})$] with the requirement of an associated isolated photon. The data are used to test the electroweak sector of the Standard Model and search for evidence for new phenomena. The measurements are used to probe the anomalous $WW\gamma$, $ZZ\gamma$ and $Z\gamma\gamma$ triple-gauge-boson couplings and to search for the production of vector resonances decaying to $Z\gamma$ and $W\gamma$. No deviations from Standard Model predictions are observed and limits are placed on anomalous triple-gauge-boson couplings and on the production of new vector meson resonances.
Measurements of $W\gamma$ and $Z\gamma$ production in $pp$ collisions at $\sqrt{s} = 7$ TeV with the ATLAS detector at the LHC

(ATLAS Collaboration)

(Dated: August 21, 2012)

The integrated and differential fiducial cross sections for the production of a $W$ or $Z$ boson in association with a high-energy photon are measured using $pp$ collisions at $\sqrt{s} = 7$ TeV. The analyses use a data sample with an integrated luminosity of 4.6 fb$^{-1}$ collected by the ATLAS detector during the 2011 LHC data-taking period. Events are selected using leptonic decays of the $W$ and $Z$ bosons $[W(e\nu,\mu\nu)$ and $Z(\ell^+\ell^-,\mu^+\mu^-,\nu\bar{\nu})]$ with the requirement of an associated isolated photon. The data are used to test the electroweak sector of the Standard Model and search for evidence for new phenomena. The measurements are used to probe the anomalous $WW\gamma$, $ZZ\gamma$ and $Z\gamma\gamma$ triple-gauge-boson couplings and to search for the production of vector resonances decaying to $Z\gamma$ and $W\gamma$. No deviations from Standard Model predictions are observed and limits are placed on anomalous triple-gauge-boson couplings and on the production of new vector meson resonances.

I. INTRODUCTION

The Standard Model (SM) has proved to provide an accurate description of the production of elementary particles observed in high energy physics experiments. The interactions of $W$ and $Z$ bosons with photons are particularly interesting as they test the self-couplings of these bosons as predicted by the non-Abelian $SU(2)_L \times U(1)_Y$ gauge group of the electroweak sector. In particular, the high-energy proton–proton collisions provided by the LHC explore the production of $W\gamma$ and $Z\gamma$ pairs in a new energy domain. The high center-of-mass energy also allows searches for new particles, for example, techni-mesons which are predicted in technicolor models [1, 2], that decay to these final states.

The measurements presented here are improvements on previous studies of the hadroproduction of $W\gamma$ and $Z\gamma$ pairs, as more precise measurements are performed with a larger data sample. The events used for the measurements were recorded in 2011 by the ATLAS detector [3] from 4.6 fb$^{-1}$ of $pp$ collisions at a center-of-mass energy of 7 TeV. The diboson candidate events are selected from the production processes $pp \rightarrow \ell\nu\gamma + X$ ($\ell = e, \mu$), $pp \rightarrow \ell^+\ell^-\gamma + X$ and $pp \rightarrow \nu\bar{\nu}\gamma + X$.

These final states include the production of $W$ and $Z$ bosons with photon bremsstrahlung from the charged leptons from the $W$/$Z$ boson decays in addition to the $W\gamma$ and $Z\gamma$ diboson events of primary interest. In the SM, the latter originate from $W$ and $Z$ boson production with photons radiated from initial-state quarks (prompt photons), photons from the fragmentation of secondary quarks and gluons into isolated photons, and from photons radiated directly by $W$ bosons. The diagrams of these production mechanisms are shown in Fig. 1. Theories beyond the SM, such as technicolor, predict the decay of narrow resonances to $W\gamma$ or $Z\gamma$ pairs. The data analyses presented here provide differential distributions of relevant kinematic variables, corrected for detector effects, allowing the search for deviations from the SM predictions to be made with high sensitivity.

Previous measurements of $W\gamma$ and $Z\gamma$ final states from $p\bar{p}$ and $pp$ production have been made at the Tevatron, by the CDF [4] and DØ [5, 6] collaborations, and at the LHC by the ATLAS [7, 8] and CMS [9] collaborations. These experiments have set limits on anomalous triple-gauge-boson couplings (aTGCs) that are improved on by the current analysis. The limits on new vector meson resonances that are presented in this paper improve on previous limits set at the Tevatron by the DØ [10] collaboration in the $Z\gamma$ final state, and they are the first reported in the $W\gamma$ final state.

Throughout this paper the notations “$\ell\nu\gamma$,” “$\ell^+\ell^-\gamma$” and “$\nu\bar{\nu}\gamma$” specify the production channels “$pp \rightarrow \ell\nu\gamma + X$,” “$pp \rightarrow \ell^+\ell^-\gamma + X$” and “$pp \rightarrow \nu\bar{\nu}\gamma + X$” respectively, and the label “$Z$” refers to $Z/\gamma^*$. In addition, “inclusive” refers to production with no restriction on the recoil system and “exclusive” refers to production restricted to those events with no central jets with transverse energy greater than 30 GeV. Measurements of integrated cross sections and differential kinematic distributions are performed within a fiducial region of the detector. Events with high-transverse-energy photons are used to establish aTGC limits and to carry out the searches for narrow $W\gamma$ and $Z\gamma$ resonances.

This paper is organized as follows: An overview of the ATLAS detector and the data samples used is given in Section II. Section III describes the signal and background Monte Carlo samples. Section IV defines the selection criteria for $W\gamma$ and $Z\gamma$ candidates. Section V describes the event selection criteria for the physics objects such as photons, leptons, and jets. Section VI describes the event selection criteria for $W\gamma$ and $Z\gamma$ candidates. Section VII presents the background estimations. Section VIII presents the measured $V\gamma$ ($V = W$ or $Z$) fiducial cross sections. Section IX summarizes the comparisons between the measurements and SM predictions. The observed aTGC limits are presented in Section X and the limits on masses of new vector meson resonances are given in Section XI.

II. THE ATLAS DETECTOR AND THE DATA SAMPLE

The ATLAS detector is composed of an inner tracking system (ID) surrounded by a thin superconducting...
lead absorbers with liquid argon (LAr) as the active material and covers the range $|\eta| < 3.2$. In the region $|\eta| < 1.8$, a presampler detector using a thin layer of LAr is used to correct for the energy lost by electrons and photons upstream of the calorimeter. The hadronic tile calorimeter ($|\eta| < 1.7$) is a steel/scintillating-tile detector and is located directly outside the envelope of the barrel electromagnetic calorimeter. The two end-cap hadronic calorimeters have LAr as the active material and copper absorbers. The calorimeter coverage is extended to $|\eta| = 4.9$ by a forward calorimeter with LAr as active material and copper (EM) and tungsten (hadronic) as absorber material. The MS is based on three large superconducting aircore toroid magnets, a system of three stations of chambers for precise tracking measurements in the range $|\eta| < 2.7$, and a muon trigger system that covers the range $|\eta| < 2.4$.

The data used for the analyses presented in this paper were collected in 2011 from $pp$ collisions at a center-of-mass energy of 7 TeV. The total integrated luminosity is 4.6 fb$^{-1}$ with an uncertainty of 3.9% \cite{11,12}. Events were selected by triggers requiring at least one identified electron, muon, or photon. The transverse energy ($E_T$) threshold for the single-electron trigger was initially 20 GeV, and was raised to 22 GeV in the later part of 2011 to maintain a manageable trigger rate at higher instantaneous luminosity. The transverse momentum ($p_T$) threshold for the single-muon trigger was 18 GeV. Single-photon events were triggered with a transverse energy $E_T > 80$ GeV.

### III. SIGNAL AND BACKGROUND MODELING

Monte Carlo (MC) event samples, including a full simulation \cite{13} of the ATLAS detector with GEANT4 \cite{14}, are used to compare the data to the SM signal and background expectations. All MC samples are simulated with additional $pp$ interactions (pileup) in the same and neighboring bunch crossings. The number of $pp$ interactions in the same bunch crossing averages 9 and extends up to about 20, as observed in the data.

The production of $pp \rightarrow ℓνγ$ and $pp \rightarrow ℓνγ$ is modeled with the ALPGEN (2.14) generator \cite{15} interfaced to HERWIG (6.520) \cite{16} for parton shower and fragmentation processes, and to JIMMY (4.30) \cite{17} for underlying event simulation. The modeling of $pp \rightarrow ℓ^+ℓ^−γ$ and $pp \rightarrow ντγ$ processes is performed with the SHERPA (1.4.0) generator \cite{18} since the simulation of these processes is not available in ALPGEN. An invariant mass cut of $m(ℓ^+ℓ^-) > 40$ GeV is applied at the generator level when simulating the $pp \rightarrow ℓ^+ℓ^-γ$ process. The CTEQ6L1 \cite{19} and CTEQ6.6M \cite{20} parton distribution functions (PDFs) are used for samples generated with ALPGEN and SHERPA, respectively. The final-state radiation (FSR) photons from charged leptons are simulated by PHOTOS (2.15) \cite{21} for the ALPGEN sample, and by the SHERPA generator \cite{22} for the SHERPA sample. All the signal production processes,
including the quark/gluon fragmentation into photons, are simulated by these two generators. The ALPGEN sample is generated with leading-order (LO) matrix elements for final states with up to five additional partons, whereas the HERWIG sample is generated with LO matrix elements for final states with up to three additional partons. In the search for technicolor, the signal processes are simulated using PYTHIA (6.425) [25] with a LO MRST2007 [24] PDF set.

The $Z(\ell^+\ell^-)$ and $Z(\tau^+\tau^-)$ backgrounds are modeled with PYTHIA. The radiation of photons from charged leptons is treated in PYTHIA using PHOTOS. TAUOLA (1.20) [25] is used to model $\tau$ lepton decays. The POWHEG (1.0) [26] generator is used to simulate $t\bar{t}$ production and is interfaced to PYTHIA for parton showering and fragmentation. The WW and single top quark processes are modeled by MC@NLO (4.02) [27], interfaced to HERWIG for parton showering and fragmentation. The LO MRST2007 PDF set is used to simulate the $Z(\ell^+\ell^-)$, $Z(\tau^+\tau^-)$, and $W(\tau\nu)$ backgrounds, and the CT10 [28] PDF set is used in simulating $t\bar{t}$, single top quark, and WW production. The next-to-leading-order (NLO) cross-section predictions [29,30,33] are used to normalize the simulated background events. Backgrounds where a jet or an electron is misidentified as a photon are derived from data as described in Sec. VI.

IV. PHYSICS OBJECT RECONSTRUCTION

The $W$ and $Z$ bosons are reconstructed from their leptonic decays. The $e\nu\gamma$ final state consists of an isolated electron or muon, large missing transverse momentum due to the undetected neutrino, and an isolated photon. The $\ell^+\ell^-\gamma$ final state contains one $e^+e^-$ or $\mu^+\mu^-$ pair and an isolated photon. The $\nu\bar{\nu}\gamma$ final state contains at least one isolated photon and large missing transverse momentum due to the undetected neutrinos. Collision events are selected by requiring at least one reconstructed vertex with at least three charged particle tracks with $p_T > 0.4$ GeV. If more than one vertex satisfies the vertex selection requirement, the vertex with the highest sum of the $p_T^2$ of the associated tracks is chosen as the primary vertex. Physics objects for the measurement are required to be associated with the primary vertex.

An electron candidate is obtained from an energy cluster in the EM calorimeter associated with a reconstructed track in the ID. The transverse energy of electrons is required to be greater than 25 GeV. The electron cluster must lie outside the transition region between the barrel and end-cap EM calorimeters and within the overall fiducial acceptance of the EM calorimeters and the ID, so it must satisfy $|\eta| < 1.37$ or $1.52 < |\eta| < 2.47$. At the electron track’s closest approach to the primary vertex, the ratio of the transverse impact parameter $d_0$ to its uncertainty (the $d_0$ significance) must be smaller than 10, and the longitudinal impact parameter $|z_0|$ must be less than 1 mm. Tight electron identification [34] is used in the $W(e\nu\gamma)$ analysis, whereas medium identification [34] is used to select electrons in the $Z(e^+e^-\gamma)$ analysis. To reduce the background due to a jet misidentified as an electron, a calorimeter-based isolation requirement $E_T^{iso} < 6$ GeV is applied to the electron candidate. $E_T^{iso}$ is the total transverse energy recorded in the calorimeters within a cone of radius $\Delta R = 0.3$ around the electron position excluding the energy of the electron itself. $E_T^{iso}$ is corrected for leakage from the electron energy cluster’s core into the isolation cone and for contributions from the underlying event and pileup [35,36].

Muon candidates are identified by associating complete tracks or track segments in the MS to tracks in the ID [37]. Each selected muon candidate is a combined track originating from the primary vertex with transverse momentum $p_T > 25$ GeV and $|\eta| < 2.4$. It is required to be isolated by imposing $R^{iso} < 0.15$, where $R^{iso}$ is the sum of the $p_T$ of the tracks in a $\Delta R = 0.3$ cone around the muon direction, excluding the track of the muon, divided by the muon $p_T$. The $d_0$ significance must be smaller than 3, and $|z_0|$ must be less than 1 mm.

Photon candidates are based on clustered energy deposits in the EM calorimeter in the range $|\eta| < 2.37$ (excluding the calorimeter transition region $1.37 < |\eta| < 1.52$) with $E_T > 15$ GeV. Clusters without matching tracks are directly classified as unconverted photon candidates. Clusters that are matched to tracks that originate from reconstructed conversion vertices in the ID or to tracks consistent with coming from a conversion are considered as converted photon candidates. Tight requirements on the shower shapes [35] are applied to suppress the background from multiple showers produced in meson (e.g. $\pi^0$, $\eta$) decays. To further reduce this background, a photon isolation requirement $E_T^{iso} < 6$ GeV is applied. The definition of photon isolation is the same as the electron isolation described above.

Jets are reconstructed from energy observed in the calorimeter cells using the anti-$k_t$ jet clustering algorithm [38] with radius parameter $R = 0.4$. The selected jets are required to have $p_T > 30$ GeV with $|\eta| < 4.4$, and to be well separated from the lepton and photon candidates ($\Delta R_e(e/\mu/\gamma, \text{jet}) > 0.3$).

The missing transverse momentum ($E_T^{miss}$) [39] magnitude and direction are measured from the vector sum of the transverse momentum vectors associated with clusters of energy reconstructed in the calorimeters with $|\eta| < 4.9$. A correction is applied to the energy of those clusters that are associated with a reconstructed physical object (jet, electron, $\tau$ lepton, photon). Reconstructed muons are also included in the sum, and any calorimetrically

---

Footnote:

2 The definitions of tight and medium identification [34] were re-optimized for 2011 data-taking conditions. They are based on information about calorimeter shower shapes, track quality, track–calorimeter-cluster matching, particle identification information from the TRT, and a photon conversion veto.
ter energy deposits associated with them are excluded to avoid double counting.

V. Wγ AND Zγ EVENT SELECTION

The ℓνγ candidate events are selected by requiring exactly one lepton with \( p_T > 25 \) GeV, at least one isolated photon with \( E_T^γ > 15 \) GeV and \( E_T^{miss} \) above 35 GeV. In addition, the transverse mass \(^{3} T^{miss}\) of the lepton–\( E_T^{miss} \) system is required to be greater than 40 GeV. A Z-veto requirement is applied in the electron channel of the Wγ analysis by requiring that the electron–photon invariant mass \((m_{eγ})\) is not within 15 GeV of the Z boson mass. This is to suppress the background where one of the electrons from the Z boson decay is misidentified as a photon. The events selected by the criteria above are used for the inclusive Wγ cross-section measurements.

The \( ℓ⁺ℓ−γ \) candidates are selected by requiring exactly two oppositely charged same-flavor leptons with an invariant mass greater than 40 GeV and one isolated photon with \( E_T^γ > 15 \) GeV.

The \( ν\bar{ν}γ \) candidates are selected by requiring one isolated photon with \( E_T^γ > 100 \) GeV and \( E_T^{miss} > 90 \) GeV. The reconstructed photon, \( E_T^{miss} \) and jets (if jets are found) are required to be well separated in the transverse plane with \( ∆φ(E_T^{miss},γ) > 2.6 \) \(^{3} T^{miss}\) and \( ∆φ(E_T^{miss},jet) > 0.4 \), in order to reduce the \( γ+jets \) background. Events with identified electrons and muons are vetoed to reject W+jets and Wγ background. The selection criteria to identify the electrons and muons are the same as in the \( Z(ℓ⁺ℓ−)γ \) analysis.

In both the Wγ and Zγ analyses, a selection requirement \( ∆R(ℓ,γ) > 0.7 \) is applied to suppress the contributions from FSR photons in the W and Z boson decays. The events with no jets with \( E_T > 30 \) GeV are used to measure the exclusive Vγ cross sections. For Vγ production, events with a high-\( E_T \) photon tend to have more jet activity in the final state. Contributions from aTGCs also enhance Vγ production with high-\( E_T \) photons. Thus, the exclusive Vγ cross-section measurements are expected to be more sensitive to aTGC than the inclusive measurements. In the current analyses the sensitivity to aTGCs improves by ∼ 40% when measurements are performed using exclusive channels compared to inclusive channels.

VI. BACKGROUND ESTIMATION

In the measurements of ℓνγ, \( ℓ⁺ℓ−γ \) and \( ν\bar{ν}γ \) production, the background contributions are estimated either from simulation or from data. The backgrounds estimated from data include W+jets and \( γ+jets \) for the \( ℓνγ \) final state, \( Z+jets \) for the \( ℓ⁺ℓ−γ \) final state, and \( Z+jets \), multijets, \( γ+jets \) and events with an electron faking a photon for the \( ν\bar{ν}γ \) final state. The remaining backgrounds are estimated from simulation.

For the differential fiducial cross sections, the contributions from each background source are estimated in each bin used for the measurement. The sources of backgrounds and the methods of estimating them are described in the following subsections.

A. Background estimation for \( pp → ℓνγ \)

The primary backgrounds to the ℓνγ signal come from the W+jets, \( Z(ℓ⁺ℓ−) \) and \( γ+jets \) processes.

i Events from W+jets production can be misidentified as signal candidates when photons come from the decays of mesons produced in jet fragmentation (mainly \( π^0 \rightarrow γγ \));

ii \( Z(ℓ⁺ℓ−) \) events mimic the Wγ signal when one of the leptons from the Z boson decay is misidentified as a photon (in the case of the electron channel), or is not identified and the photon originates from initial-state radiation from a quark or from photon bremsstrahlung from a charged lepton;

iii Events from \( γ+jets \) production can mimic the Wγ signal when there are leptons from heavy quark decays (or, in the electron channel, when charged hadrons or electrons from photon conversions are misidentified as prompt electrons), and large apparent \( E_T^{miss} \) is created by a combination of real \( E_T^{miss} \) from neutrinos in heavy quark decays and of mis-measurement of jet energies;

iv In addition, there are background contributions from \( tt \), single top quark, WW, W(τν) and Z(ττ) processes. The \( pp → τνγ + X \) source of events is considered as a background since measurements of cross sections for \( pp → ℓνγ + X \) production are quoted for a single lepton flavor.

The background contributions from W+jets and \( γ+jets \) events in the Wγ analysis are estimated from data.

W+jets background: A two-dimensional sideband method is used for measuring the W+jets background as in Refs. \(^8\) \(^9\) \(^10\) \(^11\) with the two discriminating variables being the photon isolation and the photon identification based on the shower shape (see Fig. 2). The nonsignal regions are corrected for any contamination by signal events. A quantity \( f_x \) is defined as the ratio of photon candidates passing the photon isolation criteria to the number of candidates failing the isolation requirement. The ratio \( f_x \) is measured in W(ℓν) events with one “low quality” photon candidate, which is defined as

---

\(^3\) \( m_T = \sqrt{2p_T(ℓ) × E_T^{miss} × (1 − \cos Δφ)} \), and \( Δφ \) is the azimuthal separation between the directions of the lepton and the missing transverse momentum vector.
one that fails the full photon shower-shape selection criteria, but passes a subset of them (C/D). Monte Carlo simulation is used to correct \( f_1 \) for signal contamination in the “low quality” photon sample. The estimated contribution from \( W + \text{jets} \) in the signal region is obtained by multiplying the measured \( f_1 \) by the number of events passing all \( W \gamma \) selections, except the photon isolation requirement (region B).

The main contribution to the uncertainty in the \( W + \text{jets} \) background estimate comes from the potential bias in the \( E_T^{\text{iso}} \) shape for the fake photons in background-enriched samples due to effects from the detector (e.g. measurement of shower shapes) and physics (e.g. simulation of the underlying event). This uncertainty is found to be less than 15% using a MC \( W + \text{jets} \) sample, by comparing the \( E_T^{\text{iso}} \) shape between the “low quality” photon sample and the “high quality” photon sample. The difference is used to modify the ratio \( f_1 \), and a new \( W + \text{jets} \) background contribution in the signal region is estimated. The difference between the nominal estimate and the new estimate is taken to be the systematic uncertainty.

To estimate the uncertainty related to the selection of the background-enriched samples, two alternative selections, with tighter and looser background selection requirements based on the shower shapes are used. For the tighter selection, more shower-shape variables are required to fail the selection cuts than for the looser background-enriched samples. The \( W + \text{jets} \) background estimates from the alternative background-enriched samples are consistent with those obtained from the nominal sample, and the differences (10%-15%) are assigned as a systematic uncertainty. The changes in the background estimates from varying the photon isolation requirements by \( \pm 1 \text{ GeV} \) for the sideband (2%-4%) are also assigned as a systematic uncertainty.

\( \gamma + \text{jets} \) background: Similarly, the \( \gamma + \text{jets} \) background is estimated from data using the two-dimensional sideband method, with lepton isolation (using the measured ratio \( f_1 \)) and \( E_T^{\text{miss}} \) as the independent variables. The ratio \( f_1 \) is measured in a control sample, which requires the events to pass all the \( W \gamma \) selection criteria, except the \( E_T^{\text{miss}} \) requirement, which is inverted. The potential bias in the \( E_T^{\text{iso}} \) shape for the fake lepton in the low-\( E_T^{\text{miss}} \) background-enriched samples is found to be 10%-15% based on MC simulations. By varying the \( E_T^{\text{miss}} \) threshold, alternative control samples are obtained to evaluate the systematic uncertainties on \( f_1 \). In addition, the impact parameter requirements for the muon-candidate tracks and the shower-shape selection criteria for electron candidates are also varied to obtain alternative control samples enriched in \( \gamma + \text{jets} \) events. The differences between the \( \gamma + \text{jets} \) estimates (about 9%) from those control samples give one of the main systematic uncertainties. The change in the \( \gamma + \text{jets} \) estimates from varying the lepton isolation requirements (about 4%) is also assigned as a systematic uncertainty.

In the measurement of the differential fiducial cross section as a function of \( E_T^{\gamma} \), the sideband method is used to estimate the \( W/\gamma + \text{jets} \) backgrounds in each \( E_T^{\gamma} \) bin for the range \( 15 < E_T^{\gamma} < 60 \text{ GeV} \). Extrapolation methods are used to estimate the \( W/\gamma + \text{jets} \) background in the \( E_T^{\gamma} > 60 \text{ GeV} \) region, where few events are available. The statistical uncertainty on the background estimates become comparable to, or larger than, the systematic uncertainty at \( E_T^{\gamma} > 40 \text{ GeV} \). The extrapolation from the low to the high \( E_T^{\gamma} \) regions is done using the \( E_T^{\gamma} \) distribution shape obtained from control samples \([W(\ell \nu) \text{ events with one “low quality” photon candidate to estimate the } W + \text{jets background and } W(l\nu) \text{ events with a nonisolated lepton to estimate the } \gamma + \text{jets background}]. \) The difference between results (15%-30%) obtained from the sideband method and extrapolation methods is treated as an additional uncertainty for the high-\( E_T^{\gamma} \) bins.

To measure the differential fiducial cross sections as a function of jet multiplicity and the transverse mass of the \( W \gamma \) system, the distributions of these kinematic variables for the \( W/\gamma + \text{jets} \) backgrounds are taken from the control samples described in the previous paragraph. The \( W/\gamma + \text{jets} \) distributions are then normalized to the predicted contributions to the measurements.

**FIG. 2.** Sketch of the two-dimensional plane defining the four regions used in the sideband method. Region A is the signal region. The nonisolated control regions (B and D) are defined for photons with \( E_T^{\gamma} > 7 \) GeV. The “low quality photon identification” control regions (C and D) include photon candidates that fail the full photon shower-shape selection criteria, but pass a subset of them. For the data driven \( W + \text{jets} \) background estimation to the inclusive \( W \gamma \) measurement, about 1000 \( W + \text{jets} \) candidates are selected in the nonisolated control regions, and about 2000 \( W + \text{jets} \) candidates are selected in the “low quality photon identification” control regions.

tion criteria, and the events in the $Z(e^+e^-)+$jets control regions are selected by imposing the nominal $ev\gamma$ selection criteria, except requiring that $m_{e\nu}$ be within 15 GeV of the $Z$ boson mass, assuming one of the electrons is misidentified as a photon. A good agreement between the data and the MC simulation for the $E_T^{\text{miss}}$ distributions is found in these two $Z$ control regions, both in events with low pileup and in events with high pileup. Therefore their contributions are estimated from MC simulations. The uncertainties in $E_T^{\text{miss}}$ modeling in the $Z(t^+t^-)$ process are studied by varying the energy scale and resolution of the leptons, photons, jets, and unassociated energy clusters in the calorimeter.

Other backgrounds: The background contributions from $t\bar{t}$, $WW$, single top quark, $Z(\tau^+\tau^-)$, and $W(\tau\nu)$ processes are estimated from MC simulations. The systematic uncertainties arise mainly from theoretical uncertainties on the production cross sections of these background processes and uncertainties on the lepton, photon, jet, and $E_T^{\text{miss}}$ modeling in the simulation.

A summary of background contributions and signal yields in the $W\gamma$ analysis is given in Table I. The estimated $W+jets$ background is significantly smaller in the electron channel than in the muon channel due to the $Z$-veto requirement in the electron channel, described in Sec. VI A. The distributions of the photon transverse energy, $E_T^{\gamma}$, jet multiplicity, and three-body transverse mass [see Eq. 1] from the selected $W\gamma$ events are shown in Fig. 3. The data are compared to the sum of the backgrounds and the SM signal predictions. The distributions for the expected $W\gamma$ signal are taken from signal MC simulation and normalized to the total extracted number of signal events shown in Table I ($N_{W\gamma}^{\text{sig}}$).

B. Background estimation for $pp \rightarrow \ell^+\ell^-\gamma$

The main background to the $\ell^+\ell^-\gamma$ signal (amounting to 98%-99% of the total background) originates from events with $Z+jets$ where jets are misidentified as photons. The $Z+jets$ contamination is estimated from data using a sideband method similar to the one described in Sec. VI A. The main uncertainty (20%) is due to the bias in the $E_T^{\gamma}$ shape for the fake photons in background-enriched control samples defined by the "low quality" selection criteria. The small contribution from $tt+X$ production (mainly from $tt+\gamma$) is estimated from MC simulation. A summary of background contributions and signal yields in the $\ell^+\ell^-\gamma$ analyses is given in Table I. The distributions of the photon transverse energy, jet multiplicity, and three-body mass from the selected $Z\gamma$ events are shown in Fig. 4. The data and simulation agree within the uncertainty of the background estimate.

C. Background estimation for $pp \rightarrow \nu\bar{\nu}\gamma$

Background to the $\nu\bar{\nu}\gamma$ signal originates mainly from the following processes:

i. $W(e\nu)$ events, when the electron is misidentified as a photon;

ii. $Z(\nu\bar{\nu})$+jets and multijet events, when one of the jets in the event is misidentified as a photon;

iii. $\tau\gamma$ and $\bar{\nu}\gamma$ events from $W\gamma$ production, when the $\tau$ decays into hadrons or when the electron or muon from $\tau$ or $W$ decay is not reconstructed;

iv. $\gamma$+jets events, when large apparent $E_T^{\text{miss}}$ is created by a combination of real $E_T^{\text{miss}}$ from neutrinos in heavy quark decays and mismeasured jet energy.

$W(e\nu)$ background: To estimate the background contribution from $W(e\nu)$, the following dedicated studies are performed to determine the probability for an electron to be identified as a photon in the final state. A sample of $Z \rightarrow e^+e^-$ event candidates, with one of the $e$ replaced by a photon, taken from data is used to estimate the fraction of electrons from the $Z$ boson decay that are reconstructed as photons. The events are selected if the reconstructed invariant mass of the photon and the electron is close to the $Z$ mass. This fraction $(f_{e\rightarrow\gamma})$ increases from 2% to 6% as $|\eta|$ increases. These fake rates are used to determine the $W(e\nu)$ background in the signal region, by weighting the electron candidates in the control region with the misidentification rate corresponding to their $|\eta|$. The events in the $W(e\nu)$ control region are selected by nominal $\nu\nu\gamma$ selection criteria, except an electron is used instead of a photon in the final state. The data-driven estimates of the $W(e\nu)$ background are limited mainly by the accuracy of the measurement of the misidentification rate. The combined statistical and systematic uncertainties of the determination of $f_{e\rightarrow\gamma}$ are used to evaluate the systematic uncertainties of the $W(e\nu)$ background estimate.

$Z(\nu\bar{\nu})$+jets and multijets backgrounds: A data-driven method similar to the one described in Sec. VI A is used to determine the background contribution from $Z(\nu\bar{\nu})$+jets and multijets events. The main systematic uncertainty (20%) comes from the differences between $f_\gamma$ values measured in various control samples obtained by varying the selection criteria for "low quality" photons.

$W\gamma$ background: Misidentified events from the $W\gamma$ process are one of the dominant background contributions to the $\nu\bar{\nu}\gamma$ signal. A large fraction (about 65%) of the $W\gamma$ contamination comes from $\tau\nu\gamma$ events. The branching fractions of the $\tau$ decay modes are well known and modeled by MC simulation. The main uncertainty on the $\tau\nu\gamma$ contamination is due to the uncertainty on the MC normalization factor. By assuming lepton universality for the $W$ boson decays, the MC scale factor for $\tau\nu\gamma$ events and its uncertainty are taken from the measurement of $\ell\nu\gamma$ events. The scale factor is defined.

TABLE III. Total number of events in the data \((N_{Z\gamma}^{obs})\), expected number of background events from various SM processes, and observed signal yields \((N_{Z\gamma}^{sig})\) after all \(\nu\bar{\nu}\gamma\) selection criteria are applied for inclusive \((N_{jet} \geq 0)\) and exclusive \((N_{jet} = 0)\) events. \(N_{Z\gamma}^{obs}\) is defined as the difference between \(N_{Z\gamma}^{obs}\) and the total number of expected background events. The first uncertainty is statistical and the second uncertainty represents an estimate of the systematic effects.

To correct for the yield of \(\nu\bar{\nu}\gamma\) events estimated by MC simulation to match the \(\nu\bar{\nu}\gamma\) event yield measured in data as shown in Table I. About 35% of \(W\gamma\) contamination comes from \(\nu\bar{\nu}\gamma\) events. Most of the \(\nu\bar{\nu}\gamma\) contamination consists of events with a low-\(E_T\) lepton below 25 GeV (70%) or with a high-\(E_T\) central lepton that failed to pass the identification or isolation criteria (20%). Less than 5% of \(\nu\bar{\nu}\gamma\) contamination comes from events with a forward lepton outside the detector’s fiducial volume.

\(\gamma+\text{jets background:}\) Due to the high-\(E_T^{miss}\) requirement in \(\nu\bar{\nu}\gamma\) event selection, \(\gamma+\text{jets} \) contamination is sup-
pressed, especially in the exclusive measurement with a jet veto cut. In order to measure this background from data, a sample is selected by applying all signal-region selection criteria except for requiring \(\Delta\phi(E_T^{miss}, \text{jet})< 0.4\). By requiring the \(E_T^{miss}\) direction to be close to the jet direction, the selected events in the control region are dominated by \(\gamma+\text{jets}\) background. The yield of \(\gamma+\text{jets}\) obtained in control regions is then scaled by an extrapolation factor to predict the \(\gamma+\text{jets}\) background yield in the signal region, where the extrapolation factor is taken from a \(\gamma+\text{jets}\) MC sample. By varying the \(E_T^{miss}\) threshold from 60 GeV to 100 GeV and varying the jet multiplicity requirement for the events from \(N_{jet} \geq 0\) to \(N_{jet} \geq 1\), alternative control samples are obtained to evaluate the systematic uncertainties. The main systematic uncertainty in the \(\gamma+\text{jets}\) estimate comes from the different background yields in different control regions. The systematic uncertainty on the extrapolation factor is obtained by comparing the predictions from SHHERPA and PYTHIA \(\gamma+\text{jets}\) MC samples and varying the energy scale and resolution for jets and \(E_T^{miss}\) in MC samples.

\(\text{Other backgrounds:}\) Background contributions from other processes are determined from MC samples. The contributions from \(Z(\tau^+\tau^-)\gamma\), and \(t\bar{t}\) are found to be small (about 1% of the total background). The contributions from the other processes such as \(Z(\ell^+\ell^-), \gamma\gamma\), and diboson production, are found to be negligible due to the strict cuts applied to the \(E_T^{miss}\) and the photon transverse energy.

To investigate the possibility of non-collision backgrounds, the distributions of the direction of flight as
as the quality criteria (e.g., shower shapes) of the photon candidates in data are compared to those expected from the signal simulation to search for discrepancies. The direction of flight, which is determined by using the depth segmentation of the EM calorimeter, can show if the photon appears to be coming from a vertex other than the primary vertex. The spectra of the direction of flight as well as the quality criteria are found to be completely consistent with those photons produced in events with real photons [e.g. $W(\ell\nu) + \gamma$ and $Z(\ell^+\ell^-) + \gamma$] leading to the conclusion that if there are noncollision background events, they are negligible.

A summary of background contributions and signal yields in the $\nu\bar{\nu}\gamma$ analysis is given in Table III. The photon transverse energy, the jet multiplicity and the missing transverse energy distributions from the selected $\nu\bar{\nu}\gamma$ events are shown in Fig. 3.
VII. CROSS-SECTION MEASUREMENTS

The cross-section measurements for the $W\gamma$ and $Z\gamma$ processes are performed in the fiducial region, defined at particle level using the object and event kinematic selection criteria described in Sec. [V]. They are then extrapolated to an extended fiducial region (defined in Table [IV]) common to the electron and muon final states. In this analysis, particle level refers to stable particles, defined as having lifetimes exceeding 10 ps, that are produced from the hard scattering or after the hadronization but before their interaction with the detector. The extrapolation corrects for the signal acceptance losses in the calorimeter transition region ($1.37 < |\eta| < 1.52$) for electrons and photons, and in the high-$\eta$ region ($2.4 < |\eta| < 2.47$) for muons. It also corrects for the $Z$-veto requirement in the $W\gamma$ electron channel, for the transverse mass selection criteria in both channels in the $W\gamma$ analysis, and for the acceptance loss due to the selection requirements on $\Delta \phi(E_T^{\text{miss}}, \gamma)$ and $\Delta \phi(E_T^{\text{miss}}, \text{jet})$ in the $\nu \nu \gamma$ analysis. Jets at particle level are reconstructed in MC-generated events by applying the anti-$k_t$ jet reconstruction algorithm with a radius parameter $R = 0.4$ to all final-state stable particles. To account for the effect of final-state

FIG. 4. Distribution for $e^+e^-\gamma$ candidate events combining the electron and muon channels of (a) the photon transverse energy, (b) the jet multiplicity, and (c) the three-body mass distribution. The selection criteria are defined in Sec. [V] in particular, the photon transverse energy is required to be $E_T^{\gamma} > 15$ GeV, except for panel (c) where it is required to be $E_T^{\gamma} > 40$ GeV. The distributions for the expected signals are taken from the SHERPA MC simulation and scaled by a global factor (~ 1.0) such that the total contribution from the predicted signal and background is precisely normalized to the data. The ratio of the number of candidates observed in the data to the number of expected candidates from signal and background processes is also shown. Only the statistical uncertainties on the data are shown for these ratios. The histograms are normalized by their bin width.
QED radiation, the energy of the generated lepton at particle level is defined as the energy of the lepton after radiation plus the energy of all radiated photons within a $\Delta R < 0.1$ cone around the lepton direction. Isolated photons with $e_p^\gamma < 0.5$ are considered as signal, where $e_p^\gamma$ is defined at particle level as the sum of the energy carried by final state particles in a $\Delta R < 0.4$ cone around the photon direction (not including the photon) divided by the energy carried by the photon.

\[ e_p^\gamma = \frac{\sum E_{miss}}{E_{miss}} \]

A. Integrated fiducial cross section

The cross-section measurements for the processes $pp \rightarrow \ell \nu \gamma + X$ and $pp \rightarrow (\ell^+ \ell^- \gamma/\nu \bar{\nu} \gamma) + X$ are calculated as

\[ \sigma_{ext-fid}^{pp \rightarrow \ell \nu \gamma}(\ell^+ \ell^- \gamma/\nu \bar{\nu} \gamma) = \frac{N_{V\gamma}^{\text{sig}}}{A_{V\gamma} \cdot C_{V\gamma} \cdot \int L dt} \]

where

i $N_{W\gamma}^{\text{sig}}$ and $N_{Z\gamma}^{\text{sig}}$ denote the number of background-subtracted signal events passing the selection criteria of the $W\gamma$ and $Z\gamma$ analyses. These numbers are listed in Tables I, II and III.

ii $\int L dt$ is the integrated luminosity for the channels of interest (4.6 fb$^{-1}$).

iii $C_{V\gamma}$ is defined as the number of reconstructed MC events passing all selection requirements divided by

\[ C_{V\gamma} = \frac{N_{V\gamma}^{\text{sig}}}{N_{V\gamma}^{\text{ext}}} \]
TABLE IV. Definition of the extended fiducial region where

- Leptons: $p_T^p > 25$ GeV, $p_T^\mu > 25$ GeV, $N_\ell = 1$, $N_{\ell^+} = 1$, $N_{\ell^-} = 1$, $N_0 = 0$
- Bosons: $p_T^C > 35$ GeV
- Photons: $E_T^\gamma > 15$ GeV, $E_T^\gamma > 15$ GeV, $E_T^\gamma > 100$ GeV, $|\eta^\gamma| < 2.37$, $\Delta R(\ell, \gamma) > 0.7$, $\epsilon_h^\gamma < 0.5$
- Jet: $E_T^{jet} > 30$ GeV, $|\eta^{jet}| < 4.4$, $\Delta R(\ell/\mu, \gamma/jet) > 0.3$

Inclusive: $N_{jet} \geq 0$, Exclusive: $N_{jet} = 0$

The cross sections are evaluated; $p_T^p$ is the transverse momentum of the neutrino from $W$ decays; $p_T^\mu$ is the transverse momentum of the $Z$ boson that decays into two neutrinos; $N_\ell$ is the number of leptons in one event; $\epsilon_h^\gamma$ is the photon isolation fraction.

The number of generated events at particle level within the fiducial region. These ratios, which are corrected with scale factors to account for small discrepancies between data and simulation, are shown in Table V.

iv A$_{V\gamma}$ are the acceptances, defined at particle level as the number of generated events found within the fiducial region divided by the number of generated events within the extended fiducial region. These acceptances are listed in Table V.

The correction factors C$_{V\gamma}$ are determined by using W/Z + $\gamma$ signal MC events, corrected with scale factors to account for small discrepancies between data and simulation. These discrepancies include the differences in the lepton and photon reconstruction, identification, and isolation efficiencies, as well as trigger efficiencies.

Table VI summarizes the systematic uncertainties on C$_{V\gamma}$ from different sources, on the signal acceptance A$_{V\gamma}$, and on the background estimates. The dominant uncertainties on C$_{V\gamma}$ come from photon identification and isolation efficiency. The photon identification efficiency is determined from the signal MC samples where the shower-shape distributions of the photon are corrected to account for the observed small discrepancies between data and simulation. The systematic uncertainty is determined by comparing the corrected nominal value from MC simulation with the efficiency measurement using a pure photon sample from radiative $Z$ decays in data [36]. The uncertainty on the photon identification efficiency is found to be about 6% for all V$\gamma$ measurements. By doing a similar study, the uncertainty on the photon isolation efficiency is found to be less than 3%.

The uncertainties coming from the jet energy scale (JES) and resolution (JER) are important for all exclusive V$\gamma$ measurements. Uncertainties associated with the JES and JER affect the efficiency of the jet veto criteria and have an impact on E$_T^{miss}$. By separately varying the JES and JER within one standard deviation and propagating them to the E$_T^{miss}$, the uncertainties on C$_{V\gamma}$ due to these effects are found to be less than 4% for exclusive $\ell\nu\gamma$, and 3% for exclusive $\ell^+\ell^-\gamma$ and $\nu\nu\gamma$ measurements.

The uncertainties on energy scale and resolution for unassociated energy clusters in the calorimeter and for additional pp collisions are propagated to E$_T^{miss}$, with an impact on C$_{V\gamma}$ of less than 2% for the $\ell\nu\gamma$ and $\nu\nu\gamma$ measurements.

The muon momentum scale and resolution are studied by comparing the invariant mass distribution of $Z \rightarrow \mu^+ \mu^-$ events in data and MC simulation [37]. The impact on $\ell\nu\gamma$ and $\ell^+\ell^-\gamma$ signal events due to the muon momentum scale and resolution uncertainty is smaller than 1%. The uncertainties due to the EM energy scale and resolution, which affect both the electron and photon, are found to be 2%-3%.

The efficiencies of the lepton selections, and the lepton triggers, are first estimated from the signal MC events and then corrected with scale factors derived using high-purity lepton data samples from W and Z boson decays to account for small discrepancies between the data and the MC simulation [34,35,37,44]. In the $\ell\nu\gamma$ and $\ell^+\ell^-\gamma$ measurement, the uncertainty due to lepton identification and reconstruction is found to be about 2% in the electron channel, and less than 1% in the muon channel, and the uncertainty due to lepton isolation is found to be less than 2% in the electron channel and less than 0.5% in the muon channel.

The uncertainty due to single-muon trigger efficiencies is 2% for $\ell\nu\gamma$ and 0.6% for $\ell^+\ell^-\gamma$, while the uncertainty from single-electron trigger efficiencies is 0.7% for $\ell\nu\gamma$ and 0.1% for $\ell^+\ell^-\gamma$ [37]. The uncertainty from photon trigger efficiencies for $\nu\nu\gamma$ is 1%.

The systematic uncertainties for A$_{V\gamma}$ are dominated by PDF uncertainties (<0.8%), by the renormalization and factorization scale uncertainties (<0.5%) and by the uncertainties on the size of the contributions from fragmentation photons (<0.3%). The PDF uncertainty is estimated using the CT10 error eigenvectors at their 90% confidence-level (C.L.) limits and rescaled appropriately to 68% C.L., with variations of $\alpha_s$ in the range 0.116–0.120. The renormalisation and factorisation scales are varied by factors of 2 around the nominal scales to evaluate the scale-related uncertainties.

The cross-section measurements of each leptonic decay channel and the combined (electron, muon) channels are extracted using a likelihood method. A negative log-likelihood function is defined as

$$-\ln L(\sigma, \mathbf{x}) = \sum_{i=1}^{n} -\ln \left( \frac{e^{-(N_i^*(\sigma, \mathbf{x}) + N_i^0(\mathbf{x}))} \times (N_i^*(\sigma, \mathbf{x}) + N_i^0(\mathbf{x}))^{N_i^{obs}}}{(N_i^{obs})!} \right) + \frac{\mathbf{x} \cdot \mathbf{x}}{2},$$

(2)
The expression inside the natural logarithm in Eq. (2) is the Poisson probability of observing \( N^i_{\text{obs}} \) events in channel \( i \) when \( N^i_{\text{s}} \) signal and \( N^i_{\text{b}} \) background events are expected. The nuisance parameters \( \mathbf{x} \), whose distribution is assumed to be Gaussian, affect \( N^i_{\text{s}} \) and \( N^i_{\text{b}} \) as

\[
N^i_{\text{s}}(\sigma, \mathbf{x}) = N^i_{\text{s}}(\sigma, 0)(1 + \sum_k x_k S^i_k),
\]

\[
N^i_{\text{b}}(\mathbf{x}) = N^i_{\text{b}}(0)(1 + \sum_k x_k B^i_k),
\]

where \( S^i_k \) and \( B^i_k \) are, respectively, the relative systematic uncertainties on the signal and background due to the \( k \)th source of systematic uncertainty. The quantity \( n \) in Eq. (2) is the number of channels to combine. By varying the nuisance parameters \( \mathbf{x} \), the negative log-likelihood in Eq. (2) is minimized to obtain the most probable value of the measured cross section.

For the combination, it is assumed that the uncertainties on the lepton trigger and identification efficiencies are uncorrelated between different leptonic decay channels. All other uncertainties, such as the ones on the photon efficiency, background estimation, and jet energy scale, are assumed to be fully correlated. The measured production cross sections in the extended fiducial region defined in Table [IV] for the \( \ell\nu\gamma \), \( \ell^+\ell^-\gamma \) and \( \nu\bar{\nu}\gamma \) processes are summarized in Table [VIII]. These cross-section measurements are the most extensive made to date for the study of \( V+\gamma \) production at the LHC.

### B. Differential fiducial cross section

Differential cross sections provide a more detailed comparison of the theoretical predictions to measurements, allowing a generic comparison of the kinematic distributions both in shape and normalization of the spectrum. For this purpose, the measured distributions are corrected to the underlying particle-level distributions by unfolding the effects of the experimental acceptance and resolution. A Bayesian iterative unfolding technique [45] is used. In the unfolding of binned data, effects of the experimental resolution are expressed by a response matrix, each element of which is the probability of an event in the \( i \)th bin at the particle level being reconstructed in the \( j \)th measured bin. In the iterative Bayesian unfolding, the initial prior for the underlying particle-level distribution is chosen to be the particle-level spectrum from the signal Monte Carlo sample. The posterior probability is obtained by Bayesian theory given the prior distribution, the measured distribution, and the response matrix. The posterior is then used by the unfolding algorithm as a prior for the next iteration. Two iterations are used in the unfolding procedure because tests have shown that the unfolded spectrum becomes insensitive to the initial prior probability after two iterations.

The Bayesian unfolding is not sensitive to the MC simulation modeling of the spectrum shape. To estimate a potential bias due to MC modeling, the unfolding method was tested using a data-driven closure test. In this test the particle-level spectrum in the MC simulation is reweighted and convolved through the folding matrix such that significantly improved agreement between the data and the reconstructed spectrum from the MC simulation is attained. The reweighted, reconstructed spectrum in the MC simulation is then unfolded using the same procedure as for the data. The comparison of the result with the reweighted particle-level spectrum from the MC simulation provides the estimate of the bias due to the MC modeling. The typical size of the bias is less than 0.5%.

The \( E_T^\gamma \) bins are chosen to be large compared to the detector resolution to minimize migration effects and to maintain a sufficient number of events in each bin.

The differential fiducial cross section is then defined in Eq. (5), where \( x \) is the variable of the measurement, \( dx \) is the width of the \( i \)th bin of \( x \), and \( N^\text{unfold}_{i} \) is the unfolded number of events in the \( i \)th bin.

\[
\frac{d\sigma}{dx} = \frac{N^\text{unfold}_{i}}{\int E_T^\gamma \frac{d\sigma}{dE_T^\gamma} \cdot dx}.
\]

Fig. [6] shows the differential fiducial cross sections as a function of \( E_T^\gamma \) in \( V+\gamma \) processes with the inclusive selection and with the exclusive zero-jet selection, as well as a comparison to the SM prediction. The corresponding numerical values \( (\frac{d\sigma}{dE_T^\gamma}) \) are summarized in Table [VIII].

The systematic uncertainties on the differential fiducial cross sections are dominated by the uncertainties on the \( W+\text{jet}, \gamma+\text{jet}, Z(\ell^+\ell^-) \) background normalization, on the photon identification, and on the EM and jet energy scales. The statistical uncertainties on the spec-
the resulting changes in the unfolded spectrum. The systematic uncertainties are propagated through the unfolding procedure by performing pseudoexperiments. Pseudoexperiments are generated by fluctuating the content of each bin in the data spectrum according to a Poisson distribution with a mean that is equal to the bin content. The content of the response matrix is also fluctuated in pseudoexperiments according to their statistical uncertainties. The unfolding procedure is then applied to each pseudoexperiment, and the standard deviation of the unfolded results is taken as the statistical uncertainty. The systematic uncertainties on the spectrum are evaluated by varying the response matrix for each source of uncertainty and by combining the resulting changes in the unfolded spectrum.

The normalized differential fiducial cross section \( \frac{1}{2} \times \frac{d\sigma}{dx} \) and \( \frac{1}{2} \times d\sigma_i(x) \), where \( \sigma = \sum \sigma_i(x) = \int \frac{d\sigma}{dx} dx \) and \( x \) is the variable under consideration such as \( E_T^{\gamma} \) is also provided for shape comparisons. Some generators (SHERPA and ALPGEN) can provide precise predictions for the kinematic variable shapes but are less accurate for the normalization. Table VII shows the normalized differential fiducial cross sections as a function of \( E_T^{\gamma} \) for the \( \ell^+\ell^- \gamma \) processes.

The normalized cross sections measured in bins of jet multiplicity in \( V\gamma \) events are presented in Table VII and Table IX. The measurements are performed in the extended fiducial phase spaces defined in Table IV with \( E_T^{\gamma} > 0 \) (exclusive \( N_{\text{jet}} = 0 \)) \( V\gamma \) measurement.

**TABLE VII.** Measured cross sections for the \( V\gamma \) process at \( \sqrt{s} = 7 \) TeV in the extended fiducial region defined in Table IX. The statistical uncertainty of each measurement corresponds to the statistical uncertainty of the data sample used by the measurement. The SM predictions from **mcfm**, calculated at NLO, are also shown in the table with systematic uncertainties. All **mcfm** predictions are corrected to particle level using parton-to-particle scale factors as described in Sec. VIII.
FIG. 6. Measured $E_T^\gamma$ differential cross sections of (a) the $pp \to \ell\nu\gamma$ process and of (b) the $pp \to \ell^+\ell^-\gamma$ process, using combined electron and muon measurements in the inclusive ($N_{\text{jet}} \geq 0$) and exclusive ($N_{\text{jet}} = 0$) extended fiducial regions. The lower plots show the ratio of the data to the predictions by different generators. The Monte Carlo uncertainties are shown only in the ratio plots. The cross-section predictions of the SHERPA and ALPGEN generators have been scaled by a global factor to match the total number of events observed in data. The global factor is 1.5 for the ALPGEN $\ell\nu\gamma$ signal sample and 1.0 for the SHERPA $\ell^+\ell^-\gamma$ signal sample. No global factor is applied for MCFM predictions.
15 GeV for the low-\(E_T\) region, and with \(E_T^\gamma > 60\) GeV for the high-\(E_T\) region. The systematic uncertainties on the jet multiplicity measurement are dominated by the uncertainties on the jet energy scale, the jet energy resolution and the background shape.

The transverse mass \(m_T^{W\gamma}\) spectrum and the invariant mass \(m^{Z\gamma}\) spectrum are also measured in the \(\ell\nu\gamma\) and in the \(\ell^+\ell^-\gamma\) processes, respectively. The transverse mass is defined in Eq. (6), where \(m_T\) is the invariant mass of the lepton–photon system:

\[
(m_T^{W\gamma})^2 = (\sqrt{m_T^2 + |p_T(\gamma) + p_T(\ell)|^2 + E_T^{\text{miss}}})^2 - |p_T(\gamma) + p_T(\ell) + E_T^{\text{miss}}|^2.
\]

These measurements are performed in the extended fiducial phase space defined in Table IV with \(E_T^\gamma > 40\) GeV. The distribution of \(m_T^{W\gamma}\) for the \(\ell\nu\gamma\) candidates is shown in Fig. 3(d); the expected numbers of signal and background events are also shown. The unfolded \(m_T^{W\gamma}\) spectrum is presented in Fig. 3(a) and Table VIII. The systematic uncertainties of \(m_T^{W\gamma}\) spectrum are dominated by the uncertainties on the EM energy scale, the jet energy scale, the \(E_T^{\text{miss}}\) energy scale and the background shape.

The distribution of \(m^{Z\gamma}\) for the \(\ell^+\ell^-\gamma\) candidates is presented in Fig. 4(c), together with the expected \(m^{Z\gamma}\) distributions of the signal and background events. The unfolded \(m^{Z\gamma}\) spectrum is presented in Fig. 3(b) and Table VIII. The uncertainties in the \(m^{Z\gamma}\) spectrum measurement arise predominantly from the uncertainties on the EM energy scale.

VIII. COMPARISON TO THEORETICAL PREDICTIONS

To test the predictions of the SM, the cross-section measurements of \(pp \to \ell\nu\gamma + X\), \(pp \to \ell^+\ell^-\gamma + X\) and \(pp \to \nu\bar{\nu}\gamma + X\) production are compared to NLO and LO calculations using the MCFM [19] program. Version 6.3 of MCFM includes cross-section predictions for the production of \(W\gamma\) and \(Z\gamma\) at NLO and for \(W\gamma\) at LO, and for \(Z\gamma\) production the predictions are at NLO for both \(Z\gamma\) and \(Z\gamma\) at LO for \(Z\gamma\) with one or two partons. Finally, \(\nu\bar{\nu}\gamma\) production is calculated at NLO for zero partons and LO for one parton.

Measurements of inclusive \(\ell\nu\gamma\) production are compared to the NLO \(W\gamma\) prediction with no restriction on the associated quark/gluon. Exclusive \(\ell\nu\gamma\) production is compared to the same NLO prediction by requiring no parton with \(|y| < 4.4\) and \(p_T > 30\) GeV in the final state. Similarly, measurements of inclusive \(\ell^+\ell^-\gamma\) production are compared directly to the NLO \(Z\gamma\) prediction while the exclusive \(\ell\nu\gamma\) measurement is compared to the prediction with no additional parton with \(|y| < 4.4\) and \(p_T > 30\) GeV. The exclusive cross section for \(\ell^+\ell^-\gamma\) production with exactly one jet with \(|y| < 4.4\) and \(p_T > 30\) GeV is compared to the NLO \(Z\gamma +\) one-parton prediction with the same kinematic restriction on the single parton. Production of \(\ell^+\ell^-\gamma\) with exactly two jets with \(|y| < 4.4\) and \(p_T > 30\) GeV is compared to the LO \(Z\gamma +\) two-parton prediction. The cross sections for \(\nu\bar{\nu}\gamma\) production are calculated in a similar manner using the MCFM NLO prediction for \(\nu\bar{\nu}\gamma +\) zero partons.

All the MCFM predictions include \(W\) and \(Z\) boson production with photons from direct \(W\gamma\) and \(Z\gamma\) diboson production, from final-state radiation off the leptons in the \(W/Z\) decays and from quark/gluon radiation using the BFGSetII [20] photon fragmentation function. Event generation is done using the default electroweak parameters in the MCFM program and the parton distribution functions CT10 [29]. The renormalization, factorization and photon fragmentation scales are set equal to \(\sqrt{M_V^2 + E_T^{\gamma}}\). Photon isolation is defined using the fractional energy carried by partons in a cone \(\Delta R = 0.4\) about the photon direction. The fractional parton energy \(\epsilon_h\) in the isolation cone (excluding the photon’s energy) is required to be less than 0.5. The kinematic requirements for the parton-level generation are the same as those chosen at particle level for the extended fiducial cross-section measurements (see Table IV).

The parton-level cross-section uncertainties are evaluated by varying the PDFs and the renormalization and factorization scales, and by changing the definition of photon isolation. The PDF uncertainty is about 3\%–4\%. It is estimated using the CT10 error eigenvectors at their 68\% C.L. limits, and varying the \(\alpha_s\) values in the range 0.116 – 0.120. The variation of the renormalization and factorization scales from the nominal \(\sqrt{M_V^2 + E_T^{\gamma}}\) up and down by a common factor of two gives an uncertainty about 3\%–7\%. For the exclusive channels with no central jets with \(p_T\) greater than 30 GeV, the method suggested in Ref. [31] is used to estimate the uncertainty due to the energy scale of the process. The uncertainty due to the definition of photon isolation varies in the range 1\%–5\%. It is evaluated by varying the fractional parton energy \(\epsilon_h\) from 0.0 to 1.0.

To compare these NLO SM predictions to the measured cross sections, they must be corrected for the differences between the parton-level and particle-level definitions of the jet and photon isolation, as done for data. The ALPGEN+HERWIG (for \(W\gamma\)) and SHERPA (for \(Z\gamma\)) MC samples are used to estimate the parton-to-particle scale factors. The scale factor \(S_{W\gamma}\) or \(S_{Z\gamma}\) is defined as the number of simulated events passing the fiducial region selection cuts at the particle level divided by the number of simulated events passing the fiducial region selection cuts at the parton level. They increase the parton-level cross sections by up to 13\% with uncertainties that vary from 3\% to 7\% depending on the channel. A typical
value of the scale factor predicted for the $W\gamma$ inclusive phase space by the ALPGEN (SHERPA) generator is 1.05 (1.00). The uncertainties for $W\gamma$ events are evaluated by comparing the differences in predictions made using ALPGEN and SHERPA. The uncertainties for $Z\gamma$ events are evaluated by comparing two signal samples: the nominal sample uses the SHERPA generator, the alternative sample is obtained from the MADGRAPH [32] generator interfaced to PYTHIA for parton shower and fragmentation processes. A typical value of the scale factor predicted for the $Z\gamma$ inclusive phase space by the SHERPA (MADGRAPH) generator is 1.02 (1.03).

A. Integrated cross section predictions

The inclusive and exclusive production cross sections in the extended fiducial regions defined in Table [VII] for the $\ell\nu\gamma$, $\ell^+\ell^-\gamma$ and $\nu\bar{\nu}\gamma$ final states are compared as described above to the NLO predictions made by the MCFM generator. The parton-level predictions corrected to the particle level are listed in Table [VII] together with the measured cross sections for events with $E_T^{\gamma} > 15$ GeV. The MCFM NLO predictions agree well with the measured $\ell^+\ell^-\gamma$ and $\nu\bar{\nu}\gamma$ cross sections. For the $\ell\nu\gamma + X$ channel the measured exclusive ($N_{jet} = 0$) cross section is
slightly higher and the inclusive \((N_{\text{jet}} \geq 0)\) cross section significantly higher than the mcfm predictions. The discrepancy between the NLO prediction and data in the \(\ell\nu\gamma + X\) channel is due to significant contributions from multijet production that are not observed in \(\ell^+\ell^-\gamma\) as discussed in more detail below. In \(W\gamma\) production there are contributions from processes with direct photon emission from the \(W\) boson which are absent in \(Z\gamma\) production (see Fig. 11). These additional \(W\gamma\) production processes tend to have a higher jet multiplicity, and these contributions are not included in the current NLO calculations.

### B. Differential cross sections for \(pp \rightarrow \ell^+\ell^-\gamma\)

The differential cross sections for \(\ell^+\ell^-\gamma\) production can be compared to the NLO mcfm predictions and to those of the LO sherpa generator scaled with an overall normalization factor obtained from data. The \(E_T\) spectra from the inclusive and exclusive \(\ell^+\ell^-\gamma\) channel are shown in Fig. 8(b). There is good agreement between the data and the sherpa and mcfm predictions over the full \(E_T\) range. The normalized differential spectrum for the \(m_{Z\gamma}\) is compared to sherpa and mcfm in Fig. 8(b). The NLO mcfm prediction reproduces the measured \(m_{Z\gamma}\) somewhat better than the LO sherpa MC. The normalized

TABLE X. The measured differential fiducial cross sections as a function of jet multiplicity for $\ell\nu\gamma$ and $\ell^+\ell^-\gamma$ processes. The measurements are performed in the extended fiducial phase spaces defined in Table IV with $E_T^{\gamma} > 15$ GeV and with $E_T^{\gamma} > 60$ GeV. The relative uncertainty is computed from the combination of cross sections from the electron and muon channels.

jet multiplicity spectrum from the $\ell^+\ell^-\gamma + X$ events is shown in Figs. 7(c) and (d). This can be compared to the LO SHERPA generator with up to three partons, as well as to the MC@NLO generator with NLO predictions for zero and one parton, and a LO prediction for two partons. As shown in Figs. 7(c) and (d), both the MC@NLO and SHERPA generators are in good agreement with data.

C. Differential cross sections for $pp \rightarrow \ell\nu\gamma$

The background-subtracted, unfolded differential cross sections for $\ell\nu\gamma$ production can be compared to the NLO MC@NLO prediction and to both the ALPGEN and SHERPA MC generators. The predictions from MC@NLO are absolute cross sections, while those from both ALPGEN and SHERPA are scaled by an overall normalization factor obtained from data. The measured $E_T^{\gamma}$ spectrum is shown in Fig. 8(a) for both inclusive and exclusive event selections. The MC@NLO prediction agrees with the data in the lowest photon $E_T^{\gamma}$ bin but there are significant discrepancies in all higher $E_T^{\gamma}$ bins, the effect being more enhanced for the inclusive event selection. The MC generators (ALPGEN and SHERPA) reproduce the shape of the $E_T^{\gamma}$ spectrum reasonably well over the full $E_T^{\gamma}$ range. The normalized differential cross section for $\ell\nu\gamma$ as a function of $m_W^{\gamma}$ is shown in Fig. 8(a). The MC@NLO, ALPGEN, and SHERPA generators all provide a good description of the data.

The better description of ALPGEN and SHERPA compared to the MC@NLO prediction for the $E_T^{\gamma}$ spectrum from $\ell\nu\gamma$ production, can be attributed to processes with large parton multiplicities, which correspond to tree-level di-

grams of higher order in the strong coupling constant. A comparison of the jet multiplicities in the low-$E_T^{\gamma}$ region (Fig. 8(a)) and in the high-$E_T^{\gamma}$ region (Fig. 8(b)), shows that those processes with more than one parton (jet) contribute more in higher $E_T^{\gamma}$ regions. The MC@NLO NLO cross-section prediction for $\ell\nu\gamma$ production includes real parton emission processes only up to one radiated quark or gluon. The lack of higher-order QCD contributions results in an underestimate of the predicted cross sections. For the same reason, the improvement of the description by ALPGEN compared to SHERPA for the predictions of the jet multiplicity spectrum can be attributed to the fact that there are more additional hard partons included in the matrix element calculation with the ALPGEN generator.

IX. LIMITS ON ANOMALOUS TRIPLE-GAUGE-BOSON COUPLINGS

The reconstructed $E_T^{\gamma}$ distributions from $V\gamma$ events with the exclusive zero-jet selection are used to set limits on $WW\gamma$, $ZZ\gamma$, and $Z\gamma\gamma$ anomalous triple-gauge-boson coupling parameters. Assuming C and P conservation separately, the aTGCs are generally chosen as $\lambda_{\gamma}$, $\Delta\kappa_{\gamma}$ ($\Delta\kappa_{\gamma} = \kappa_{\gamma} - 1$) for the $WW\gamma$ vertex [42, 43], $h_3^Z$, $h_4^Z$ for the $ZZ\gamma$ vertex [53], and $h_4^\gamma$, $h_5^\gamma$ for the $Z\gamma\gamma$ vertex [53].

Form factors are introduced to avoid unitarity violation at very high energy. Typical choices of these form factors for the $WW\gamma$ aTGCs are: $\Delta\kappa_{\gamma}(s) = \Delta\kappa_{\gamma}/(1 + \hat{s}/\Lambda^2)^2$ and $\lambda_{\gamma}(s) = \lambda_{\gamma}/(1 + \hat{s}/\Lambda^2)^2$ [43]. For the $ZZ\gamma$ aTGCs, conventional choices of form factors are $h_3^Z(s) = h_3^Z/(1 + \hat{s}/\Lambda^2)^3$ and $h_4^Z(s) = h_4^Z/(1 + \hat{s}/\Lambda^2)^3$ [53]. Similar
choices of form factors are used for $Z\gamma\gamma$ aTGCs. Here $\sqrt{s}$ is the $W\gamma$ or $Z\gamma$ invariant mass and $\Lambda$ is the new-physics energy scale. To conserve unitarity, $\Lambda$ is chosen as 6 TeV in the $W\gamma$ analysis and 3 TeV in the $Z\gamma$ analysis. The results with energy cutoff $\Lambda = \infty$ are also presented as a comparison in the unitarity violation scheme.

For the $Z\gamma$ case, $N_{Z\gamma}^{aTGC}(h_3^3, h_4^4)$ or $N_{Z\gamma}^{aTGC}(h_3^3, h_4^4)$ are obtained in a similar way. The anomalous couplings influence the kinematic properties of $W\gamma$ and $Z\gamma$ events and thus the corrections for event reconstruction ($C_{W\gamma}$ and $C_{Z\gamma}$). The maximum variations of $C_{W\gamma}$ and $C_{Z\gamma}$ within the measured aTGC limits are quoted as additional systematic uncertainties.

The limits on a given aTGC parameter are extracted from a frequentist profile likelihood test, as explained in Sec. VII given the extended fiducial measurements. The profile likelihood combines the observed number of exclusive $V\gamma$ candidate events with $E_T^\gamma > 100$ GeV, the expected signal as a function of the aTGC [Eq. (7)] and the estimated number of background events. A point in the aTGC space is accepted (rejected) at the 95% C.L. if less (more) than 95% of the randomly generated pseudo-experiments exhibit larger profile likelihood ratio values than those observed in data. The systematic uncertainties are included in the likelihood function as nuisance parameters with correlated Gaussian constraints, and all nuisance parameters are fluctuated in each pseudoexperiment.

The limits on each aTGC parameter are obtained with the other aTGC parameters set to their SM values using a one-dimensional profile likelihood fit. The limits on each pair of aTGC are also evaluated by the same method. The 95% C.L. intervals on the charged ($\Delta \kappa_\gamma, \lambda_\gamma$) and neutral ($h_3^3, h_4^4, h_3^3, h_4^4$) anomalous couplings. The results obtained using different $\Lambda$ values are shown with all the other couplings are set to the SM values. The two numbers in each parenthesis denote the 95% C.L. interval.

Deviations of the aTGC parameters from the SM predictions would nearly all lead to an excess of high-energy photons associated with the $W$ and $Z$ bosons. Thus, measurements of the exclusive differential cross sections for $W\gamma$ production with $E_T^\gamma > 100$ GeV are used to extract aTGC limits. The cross-section predictions with aTGCs ($\sigma_{W\gamma}^{aTGC}$ and $\sigma_{Z\gamma}^{aTGC}$) are obtained from the MC generator. The number of expected $W\gamma$ events in the exclusive fiducial region ($N_{W\gamma}^{aTGC}(\Delta \kappa_\gamma, \lambda_\gamma)$) for a given aTGC strength is obtained using Eq. (7).

For the $Z\gamma$ case, $N_{Z\gamma}^{aTGC}(h_3^3, h_4^4)$ or $N_{Z\gamma}^{aTGC}(h_3^3, h_4^4)$ are obtained in a similar way. The anomalous couplings influence the kinematic properties of $W\gamma$ and $Z\gamma$ events and thus the corrections for event reconstruction ($C_{W\gamma}$ and $C_{Z\gamma}$). The maximum variations of $C_{W\gamma}$ and $C_{Z\gamma}$ within the measured aTGC limits are quoted as additional systematic uncertainties.

TABLE XII. The measured and expected 95% C.L. intervals on the charged ($\Delta \kappa_\gamma, \lambda_\gamma$) and neutral ($h_3^3, h_4^4, h_3^3, h_4^4$) anomalous couplings. The results obtained using different $\Lambda$ values are shown with all the other couplings are set to the SM values. The two numbers in each parenthesis denote the 95% C.L. interval.

X. SEARCH FOR NARROW RESONANCES

Models such as technicolor (TC) predict spin-1 mesons that have significant branching ratios to $W\gamma$ and $Z\gamma$. The discovery of a particle compatible with the SM
FIG. 9. The 95% C.L. intervals for anomalous couplings from ATLAS, D0 [5, 6], CDF [4] and LEP [54] for (a);(b) the neutral aTGCs $h^Z_3$, $h^Z_4$, $h^\gamma_3$, $h^\gamma_4$ as obtained from $Z\gamma$ events; and (c) the charged aTGCs $\Delta \kappa_\gamma$, $\lambda_\gamma$. The integrated luminosities and new-physics scale parameter $\Lambda$ are shown. The ATLAS and D0 results for the charged aTGCs measured from $W\gamma$ production are shown. Except for the coupling under study, all other anomalous couplings are set to zero. The LEP charged aTGCs results were obtained from $WW$ production, which is also sensitive to the $WWZ$ couplings and therefore required some assumptions ($\lambda_\gamma = \lambda_\gamma$, $\Delta \kappa_\gamma = (\cos^2 \theta_W / \sin^2 \theta_W)(\Delta \phi^Z - \Delta \phi^Z)$) about the relations between the $WW\gamma$ and $WWZ$ aTGCs [54–57], but did not require assumptions about the scale $\Lambda$. The combined aTGC results from the D0 experiment are obtained from $WW + WZ \rightarrow \ell\nu j j$, $WW + WZ \rightarrow \ell\nu e^+ e^-$, $W\gamma \rightarrow \ell\nu \gamma$, and $WW \rightarrow \ell\nu\ell\nu$ events [58]. The LEP limits on neutral aTGC’s are much larger than those from hadron colliders and are not included in (b).
FIG. 10. Observed 95% C.L. limits shown in the two-parameter planes for pairs of anomalous couplings (a) $h_Z^3$ and $h_Z^4$, (b) $h_3^\gamma$ and $h_4^\gamma$, and (c) $\Delta k_\gamma$ and $\lambda_\gamma$, corresponding to an infinite cutoff scale. The horizontal and vertical lines inside each contour correspond to the limits found in the one-parameter fit procedure, and the ellipses indicate the correlations between the one-parameter fits. Since all sensitivity of the measurement is contained in a single measurement of the $V\gamma$ cross sections in the high-$E_T$ regions, the likelihood ratio used to obtain the two-dimensional limits has one effective degree of freedom.

Higgs [59, 60] does not exclude the full phase space of the TC models [61–63]. Therefore, they are used here as a benchmark for new physics processes that would appear as new resonant $W\gamma$ and $Z\gamma$ states.

Exotic resonance signals and SM backgrounds are modeled using probability density functions as described below. The model is then fit to the data to test for the presence of new-physics. The electron ($e^+e^-\gamma$ and $e\nu\gamma$) and muon ($\mu^+\mu^-\gamma$ and $\mu\nu\gamma$) channels are evaluated independently in the search for $W\gamma$ and $Z\gamma$ resonances.

A. Generation and event selection

The technicolor strawman [64] model implemented in PYTHIA [23] is used to describe the production and decay of neutral and charged techni-mesons: $\omega_T \rightarrow Z\gamma$ and $\alpha_T \rightarrow W\gamma$. The following parameters are used in the event generation: number of technicolors $N_{TC} = 4$; techniquark charges $Q_U = 1$ and $Q_D = 0$ for the $Z\gamma$ final state and $Q_U = 1/2$ and $Q_D = -1/2$ for the $W\gamma$ final state; mixing angle between the techni-pions and electroweak gauge boson longitudinal component $\sin \chi = 1/3$. In addition, the mass splittings between the techni-mesons are set to be as follows: $m_{\rho_T} = m_{\omega_T}$, $m_{\alpha_T} \approx 1.1 \times m_{\rho_T}$ and $m_{\alpha_T} - m_{\rho_T} = m_W$.

This set of parameters follows those introduced for previous low scale technicolor (LSTC) [65, 66] searches in the $WZ$ and dilepton final states at the Tevatron and at

5 This parameterization of the techniquark charges is used in order to keep only the dominant $\alpha_T$ contribution in the $W\gamma$ final state to avoid the model dependence that could result from having two nearby peaks in the signal. In this way the $\rho_T$ contribution is removed.
the LHC. Using these parameters, the intrinsic widths of the resonances are of order 1 GeV, which is less than the measurement resolution. The results obtained in this study are therefore generic, as long as the resonances studied are narrow. The best limits on techni-meson production have been set at the LHC. Studying dilepton final states in 4.9 fb⁻¹ of √s = 7 TeV data, the ATLAS experiment excluded at the 95% C.L. the production of ω_T and ρ_T with masses m_{pT/ω_T} < 855 GeV. In the W Z final state, the CMS collaboration obtained an exclusion m_{pT/ω_T} < 938 GeV based on 5.0 fb⁻¹ of √s = 7 TeV data.

The searches for narrow resonances in the Wγ and Zγ final states are performed using the event selections defined in Sec. [IV] but with the photon transverse energy E_T\gamma required to be greater than 40 GeV. This choice is made to optimize the signal over SM background ratio since the decay products of a heavy resonance would be boosted. In order to keep the results as generic as possible, there is no further optimization of the cuts.

This study uses five mass points for m_{a_T} ranging from 200 GeV to 650 GeV for the Zγ channel, and seven mass points for m_{a_T} ranging from 275 GeV to 800 GeV for the Wγ channel. The signal samples are produced using the PYTHIA [22] generator interfaced to the full ATLAS GEANT4 [4] simulation with events reconstructed as for the data. Table XIII summarizes the expected number of events at each mass point after all selection cuts.

TABLE XIII. Expected number of events after all selection cuts for the generated signal mass values. The quoted uncertainties are the combined statistical and systematic uncertainties. The number of expected events is indicated only for points used in the analysis.

B. Signal modeling

For the ω_T → Zγ channel, the mZγ distribution is fit by the sum of a crystal-ball function (CB) [69] [71], which simulates the core mass resolution plus a non-Gaussian tail for low mass values, and a small wider Gaussian component that takes into account outliers in the mass distribution. The mean values of the CB and Gaussian functions are fixed to be equal. For simulated events, the mean fitted mass is found to be within 0.6 GeV of the generated resonance mass for both the μ⁺μ⁻γ and e⁺e⁻γ channels. At the reconstruction level, the full width at half maximum of the signal grows linearly from 9 GeV at m_{a_T} = 200 GeV to 30 GeV at m_{a_T} = 650 GeV. In order to scan for resonance signals in the data, mZγ mass distributions are constructed in 5 GeV steps from 200 to 650 GeV by linearly interpolating the signal line shape fit parameters for the mZγ distributions.

For the a_T → Wγ channel, the m_Wγ distribution is fit by a CB function. The mean value of the distribution is measured to be lower than the generated mass of the resonance as expected for the transverse mass. The signal resolution grows linearly from 20 GeV at m_{a_T} = 275 GeV to about 35 GeV at m_{a_T} = 800 GeV. The data are scanned for a_T → Wγ resonance signals using m_Wγ mass distributions constructed in 10 GeV steps from 275 to 800 GeV by linearly interpolating the signal line shape fit parameters for the m_Wγ distributions.

C. Background modeling

The background estimations for the Vγ resonance searches use the techniques described in Sec.[V]. The distributions of the SM predictions and the data after the event selection cuts are shown in Figs. [11](a) and (b) for m_{a_T} and Vγ, and in Figs. [12](a) and (b) for mWγ and mWγ. All the mass distributions have a broad maximum at about 150 GeV. Since the search for a resonant structure on top of a peaking background is more complex than on a falling distribution, the search is conducted only on the tails of the mZγ and mWγ mass distributions for masses larger than 180 GeV.

A blinded search is conducted in the signal region. Agreement between the data and the Monte Carlo modeling is checked in two control regions for each final state. One control region is obtained by reversing the cut on the photon transverse energy (E_Tγ < 40 GeV), and the other one by reversing the cut (< 170 GeV) on the discriminating variable (i.e.: mZγ for the Zγ channel and mWγ for the Wγ channel). Good agreement is found between data and Monte Carlo samples in these control regions.

A probability density function is created to describe the SM background in the signal region. This approach has two advantages. The shape of the SM background is taken directly from the sidebands of the fit. The probability density function obtained is also less sensitive to statistical fluctuations in the tail than techniques relying on Monte Carlo templates. For both the Wγ and Zγ channels, the overall shape of the SM background in the signal region is due to the sum of components with different shapes. A double-exponential function provides the best model in the signal region:

\[ f_{bkg} = N_{bkg} \times (e^{\alpha_1 \cdot m} + e^{\alpha_2 \cdot m}). \]
The background model is tested against a 1 fb$^{-1}$ data sample that has been previously analyzed [8]. In addition it is tested with the nominal Monte Carlo distribution and the shape of the Monte Carlo distribution obtained by varying the background composition within systematic uncertainties. The double-exponential function is found to reproduce the shapes of all these distributions properly, and is therefore used for the SM background estimation. The results of the unbinned fit to the data can be seen as the solid curve on each of the mass spectra in Figs. 11 and 12. The χ² per degree of freedom obtained for the background-only fit is close to unity for all the distributions.

FIG. 11. Three-body transverse mass for (a) the $e\nu\gamma$ and (b) $\mu\nu\gamma$ final states. The background-only fit to the data is shown. The significance quoted is defined as $\frac{(D-B)}{\sqrt{B}}$, where D is the number of data events and B the number of predicted events by the fit in the bin considered. The background distributions for the expected $\ell\nu\gamma$ events are taken from the MC simulation (generated with ALPGEN) and normalized to the extracted number of $\ell\nu\gamma$ events. The signal near the limit at $m_{\ell\ell} = 700$ GeV is also shown.

FIG. 12. Three-body invariant mass for (a) the $e^+e^-\gamma$ and (b) $\mu^+\mu^-\gamma$ final states. The background-only fit to the data is shown. The significance quoted is defined as $\frac{(D-B)}{\sqrt{B}}$, where D is the number of data events and B the number of predicted events by the fit in the bin considered. The background distributions for the expected $\ell^+\ell^-\gamma$ events are taken from the MC simulation (generated with SHERPA) and normalized to the extracted number of $\ell^+\ell^-\gamma$ events. The signal near the limit at $m_{\ell\ell} = 490$ GeV is also shown.
D. Fit model and statistical methods

The normalization, \( N_{\text{bkg}} \), and the two exponential coefficients, \( \alpha_1 \) and \( \alpha_2 \), in the SM background probability density function [Eq. (8)] are all free to vary. Another term takes into account a systematic uncertainty on the background shape. In order to ensure there are enough events in the sidebands on each side of the distribution, the SM background fit is performed in the range \([180, 800]\) GeV for the \( m_{Z\gamma} \) distribution and the range \([180, 1000]\) GeV for the \( m_{W\gamma} \) distribution. For both the data and the pseudodata experiments, a maximum log-likelihood method is used to fit the SM background probability density function to the observed event distribution.

The parameters of the signal probability density functions are all fixed to their nominal values, except the normalization of the signal and two nuisance terms that account for systematic uncertainty on the event rate and resolution as explained below. The search is conducted by scanning the \( m_{Z\gamma} \) and \( m_{W\gamma} \) distributions every 5 GeV for the \( Z\gamma \) channel and every 10 GeV for the \( W\gamma \) channel using the signal template. The normalization of the signal is fit according to the equation

\[
N_S = \sigma_{\text{Fid}} \times \epsilon_{\text{Reco}} \times \int L dt \tag{9}
\]

where the factor \( \sigma_{\text{Fid}} \), the signal fiducial cross section, is the only free parameter in this equation. The factor \( \epsilon_{\text{Reco}} \) is the signal reconstruction efficiency defined as the number of signal events passing the detector simulation and the full event selection divided by the number of events generated in the extended fiducial volume defined in Table IV but applying \( E_T > 40 \text{ GeV} \). The factor \( \epsilon_{\text{Reco}} \) accounts for the selection efficiency for signal events generated within the fiducial region. It includes, for example, effects due to the detector resolution on the lepton and photon transverse momentum and energies, and on the missing transverse energy. The normalization of the signal is determined simultaneously in the electron and muon samples for the combination. The results obtained are therefore less sensitive to statistical fluctuations in a given channel.

The parameter of interest used in this analysis is the fiducial cross section of an eventual new-physics signal. \( \sigma_{\text{Fid}} \) is scanned to check the compatibility of the data with a background-only or a signal-plus-background hypothesis.

The statistical test used is based on the profile likelihood ratio \( \mathcal{L}(\sigma_{\text{Fid}}) \), to test different hypothesized values of \( \sigma_{\text{Fid}} \). \( \mathcal{L}(\sigma_{\text{Fid}}) \) is built from the likelihood function describing the probability density function of \( m_{Z\gamma} \) and \( m_{W\gamma} \) under a signal-plus-background hypothesis and the systematic uncertainties. It combines both electron and muon final states. The statistical tests are then performed on the \( m_{W\gamma} \) and \( m_{Z\gamma} \) distributions.

The data are interpreted using a modified frequentist approach \( (CL_s) \) for setting limits. A fiducial cross section is claimed to be excluded at 95% C.L. when \( CL_s \) is less than 0.05. The probability of the background-only hypothesis, or \( p_0 \) value, is obtained using a frequentist approach. The latter gives the probability that the background fluctuates to the observed number of events or above.

E. Systematic uncertainties

Systematic uncertainties on the signal resonances are taken into account as nuisance parameters in the likelihood function used for the signal-plus-background model. Two different effects are evaluated for each source of systematic uncertainty, one for the signal event rate and one for the resolution of the signal. Each systematic effect is investigated by propagating the corresponding uncertainty to the signal sample. These are computed separately for each of the simulated resonance mass points. The four categories of systematic uncertainties and their impacts on the resonant signals are summarized below for \( m_{\text{jet}} = 300 \text{ GeV} \) in the \( Z\gamma \) channel and \( m_{\text{jet}} = 330 \text{ GeV} \) in the \( W\gamma \) channel.

The systematic effects due to the photon isolation, identification, energy resolution, and energy scale are considered. The impact of the photon geometric position in the detector on the peak resolution is also investigated to account for differences that could arise from changes of the photon pseudorapidity distribution in different theoretical models. The impact of this effect is minor and found to be about 0.2 GeV. The systematic uncertainties due to the photon reconstruction and identification contribute most to the systematic uncertainties on the signal. The total effect on the event rate is measured to be 5.7% in all the channels and contributes about 0.5 GeV to the systematic uncertainty on the resolution of the central mass of the resonance.

The systematic effects due to the electron energy resolution and electron energy scale are treated as fully correlated with the photon energy scale and resolution in the final states containing electrons (\( e^+e^-\gamma \) and \( e\nu\gamma \)). The effects of the muon energy scale and muon energy resolution, lepton identification and trigger efficiency are also investigated. The total effect of the lepton reconstruction and identification on the signal event rate is about 1.8% in the muon channels and about 1.2% in the electron channels. The effect on the peak resolution is only about 0.2 GeV.

Systematic effects due to the jet energy scale and resolution and the calibration of the missing transverse energy impact only the \( W\gamma \) channel. These are found to
cause uncertainties in the event rate of about 1% and on the peak resolution of about 1 GeV.

Finally there is a systematic uncertainty on the resonance production rate due to the 3.9% uncertainty on the integrated luminosity [11].

The effects of all the systematic uncertainties are combined in quadrature. The total systematic uncertainty on the event rate is found to be approximately 7% for all the mass points in the two channels. The systematic uncertainty on the peak resolution is found to be approximately 1(2) GeV for the \( Z\gamma \) channel at \( m_{\omega} = 300(650) \) GeV and 1.5(3) GeV at \( m_{\omega} = 330(800) \) GeV in the \( W\gamma \) channel.

Since the SM backgrounds are determined using a sideband fit to the data, uncertainties in the detector resolution and physics object reconstruction or identification have a negligible effect on the background in this analysis. However, a systematic effect from the background modeling is investigated. The method considered consists of generating background-only pseudoexperiments, and fitting each pseudodataset with the signal-plus-background model to measure a residual signal strength. For each final state, 1000 background-only pseudoexperiment samples are generated with the expected number of SM background events. For each pseudo-experiment, the signal-plus-background model is fit in steps of \( \Delta m_{\omega} = 1 \) GeV for the \( Z\gamma \) channel and \( \Delta m_{\omega} = 1 \) GeV for the \( W\gamma \) channel to measure a residual signal strength. For each mass point the mean value of the fitted strength is measured. If there is no bias in the fit model, this distribution should be centered exactly at 0. Since this is not the case, the systematic uncertainty on the background shape is taken to be the difference between 0 and the most discrepant fitted strength obtained anywhere in the mass range, augmented by the 1σ uncertainty on that fitted strength. The size of this effect is measured to be 0.2 fb for the \( Z\gamma \) analysis. This represents about 5% on the limit at low masses and up to 20% at high masses. It is measured to be 1.2 fb for the \( W\gamma \) analysis, which represents about 6% on the limit at low masses and up to 25% at high masses. This dominant systematic effect is taken into account in the fit model, by allowing the backgrounds to fluctuate like the signal, but constrained by these values.

Finally, systematic effects are evaluated on the signal theoretical cross sections due to the limited knowledge of the proton PDFs and the energy scale of the process. These are computed by comparing predictions of the nominal LO PDF set mrst2007 [24] to the 68% C.L. error set of the mstw2008 [24] PDF sets using the lhapdf framework [75]. The deviation of the predictions from the central value are added in quadrature and taken to be the size of the uncertainty. The magnitude of the PDF uncertainties on the cross sections is about 3% for the \( Z\gamma \) channel and 5% for the \( W\gamma \) channel.

F. Results

The reconstruction efficiencies, \( \epsilon_{\text{reco}} \), and the expected and observed limits on the fiducial cross section times branching ratio for the \( \omega_T \to Z\gamma \) and \( \omega_T \to W\gamma \) resonance signals are summarized in Tables XIV and XV respectively. The efficiencies are relatively flat versus the mass of the resonances.

The search is used to set 95% C.L. limits on the production of techni-mesons. Figure 13 (a) shows the expected and observed limits obtained for \( \omega_T \to Z\gamma \). The two largest deviations are observed at \( m_{\omega} = 465 \) GeV where a downward fluctuation is seen with a p-value of \( p_0 \approx 0.01 \) or a local significance of 2.7σ and at \( m_{\omega} = 205 \) GeV where an upward fluctuation is seen with a p-value of \( p_0 \approx 0.02 \) or a local significance of 2.4σ. In the \( Z\gamma \) channel the expected mass limit on the LSTC production of \( \omega_T \) is \( m_{\omega} = 483 \) GeV, while the observed limit is \( m_{\omega} = 494 \) GeV.

Figure 13 (b) shows the expected and observed limits obtained for \( \omega_T \to W\gamma \). The largest deviation is observed at \( m_{\omega} = 285 \) GeV where an upward fluctuation is recorded with a p-value of \( p_0 \approx 0.05 \) or a local significance of 2.0σ. In the \( W\gamma \) channel the expected mass limit on the LSTC production of \( \omega_T \) is \( m_{\omega} = 619 \) GeV, while the observed limit is \( m_{\omega} = 703 \) GeV.

These results are similar to those from previous searches for LSTC [67, 68] in other channels. They are more stringent than previous limits from vector resonance searches [10] in the \( Z\gamma \) final state and they are the first limits to be set from single resonance searches in the \( W\gamma \) channel.

\[
\begin{array}{cccc}
m_{\omega_T} \text{[GeV]} & \epsilon_{\text{reco}} & \text{Expected (fb)} & \text{Observed (fb)} \\
200 & 0.52 \pm 0.05 & 4.3^{+1.8}_{-1.3} & 8.3 \\
300 & 0.54 \pm 0.05 & 2.6^{+1.2}_{-1.0} & 2.2 \\
400 & 0.54 \pm 0.05 & 1.8^{+1.0}_{-0.9} & 2.2 \\
500 & 0.55 \pm 0.05 & 1.4^{+0.7}_{-0.5} & 1.5 \\
650 & 0.57 \pm 0.05 & 1.0^{+0.4}_{-0.3} & 0.9 \\
\end{array}
\]

TABLE XIV. Reconstruction efficiency in the extended fiducial volume as defined in Table XV but for \( E_T > 40 \) GeV. The expected and observed 95% C.L. upper limits for the different signal points in the \( Z\gamma \) final states are given.

XI. SUMMARY

The production of \( W\gamma \) and \( Z\gamma \) boson pairs in 7 TeV pp collisions is studied using 4.6 fb\(^{-1}\) of data collected with the ATLAS detector. The measurements are made using the leptonic decays of the \( W \) and \( Z \) bosons (\( W(e^\pm e^\mp, \mu^\pm \mu^\mp) \)) and \( Z(e^+e^-, \mu^+\mu^- , \nu\bar{n}) \)) with associated high-energy isolated photons.

The results are compared to SM predictions using the NLO parton-level generator mcfm. In general, the NLO SM predictions for the exclusive \( W\gamma \) and \( Z\gamma \) production
there are disagreements with the NLO predictions, which cross sections agree with measurements. However, as the photon $E_T^\gamma$ threshold is raised for inclusive $pp \to \ell\nu\gamma$ production, the associated jet multiplicity increases and there are disagreements with the NLO predictions, which do not include multiple quark/gluon emission. The measurements are also compared to LO MC generators (ALPGEN or SHERPA) with multiple quark/gluon emission in the matrix element calculations. These LO MC predictions reproduce the shape of the photon $E_T^\gamma$ spectrum and the kinematic properties of the leptons and jets in the $W\gamma$ and $Z\gamma$ measurements.

The measurements of exclusive $W\gamma$ and $Z\gamma$ production with $E_T^\gamma > 100$ GeV are used to constrain anomalous triple-gauge-boson couplings ($\lambda_3$, $\Delta\kappa_3$, $h_3^V$ and $h_4^V$). They are also used to search for narrow resonances in the $V\gamma$ final state with $E_T^\gamma > 40$ GeV and compared to low scale technicolor models. No evidence for physics beyond the SM is observed. The limits obtained from this study of anomalous triple-gauge-boson couplings improve on previous LHC and Tevatron results. The results of the vector resonance search are the first ones reported for the study of the $W\gamma$ final state and the most stringent in the $Z\gamma$ final state. Using the LSTC benchmark model, the production of $a_T$ is excluded up to $m_{a_T} = 703$ GeV in the $W\gamma$ mode and the production of $\omega_T$ is excluded up to $m_{\omega_T} = 494$ GeV in the $Z\gamma$ channel.

XII. ACKNOWLEDGEMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEADSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRSCT, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MES of Rus-
