Copper sensing function of Drosophila metal-responsive transcription factor-1 is mediated by a tetranuclear Cu(I) cluster

Abstract

Drosophila melanogaster MTF-1 (dMTF-1) is a copper-responsive transcriptional activator that mediates resistance to Cu, as well as Zn and Cd. Here, we characterize a novel cysteine-rich domain which is crucial for sensing excess intracellular copper by dMTF-1. Transgenic flies expressing mutant dMTF-1 containing alanine substitutions of two, four or six cysteine residues within the sequence 547CNCTNCKCDQTSDKGGDC565 are significantly or completely impaired in their ability to protect flies from copper toxicity and fail to up-regulate MtnA (metallothionein) expression in response to excess Cu. In contrast, these flies exhibit wild-type survival in response to copper deprivation thus revealing that the cysteine cluster domain is required only for sensing Cu load by dMTF-1. Parallel studies show that the isolated cysteine cluster domain is required to protect a copper-sensitive S. cerevisiae ace1Δ strain from copper toxicity. Cu(I) ligation by a Cys-rich domain peptide fragment drives the cooperative assembly of a polydentate [Cu4-S6] cage structure, characterized by a core of trigonally S3 coordinated Cu(I) ions bound by bridging thiolate ligands. While reminiscent of Cu4-L6 (L=ligand) tetranuclear clusters in copper regulatory transcription factors of yeast, the absence of significant sequence homology is consistent with convergent evolution of a sensing strategy particularly well suited for Cu(I).

ABSTRACT

Drosophila melanogaster MTF-1 (dMTF-1) is a copper-responsive transcriptional activator that mediates resistance to Cu, as well as Zn and Cd. Here, we characterize a novel cysteine-rich domain which is crucial for sensing excess intracellular copper by dMTF-1. Transgenic flies expressing mutant dMTF-1 containing alanine substitutions of two, four or six cysteine residues within the sequence 547CNCTNCKCDQTKSCHGGDC565 are significantly or completely impaired in their ability to protect flies from copper toxicity and fail to up-regulate MtnA (metallothionein) expression in response to excess Cu. In contrast, these flies exhibit wild-type survival in response to copper deprivation thus revealing that the cysteine cluster domain is required only for sensing Cu load by dMTF-1. Parallel studies show that the isolated cysteine cluster domain is required to protect a copper-sensitive S. cerevisiae ace1Δ strain from copper toxicity. Cu(I) ligation by a Cys-rich domain peptide fragment drives the cooperative assembly of a polydentate [Cu4-S6] cage structure, characterized by a core of trigonally S3 coordinated Cu(I) ions bound by bridging thiolate ligands. While reminiscent of Cu4-L6 (L = ligand) tetranuclear clusters in copper regulatory transcription factors of yeast, the absence of significant sequence homology is consistent with convergent evolution of a sensing strategy particularly well suited for Cu(I).

INTRODUCTION

Metal ions play myriad essential roles in all of biology. As a result, all cell types have evolved the ability to extract specific metal ions from their environment and ultimately maintain the intracellular concentrations of each in a range compatible with cellular needs (1). This is critical for the survival of the organism since even essential transition metal ions, e.g. Fe, Cu and Zn are toxic in excess (2). The same is true for Ni (3) and Mn (4), although acquisition of these ions ensures that specialized microorganisms are capable of surviving in a strongly acidic or potently oxidizing environment, respectively. Cu and Fe are particularly toxic since their reduced forms, Cu(I) and Fe(II), when weakly chelated in an aerobic environment, will catalyze the production of damaging hydroxyl radicals via redox cycling; as a result, the ‘free’ or bioavailable concentrations of these ions, as well as Zn, may likely be vanishingly small (5,6). The control of metal homeostasis is mediated by the balancing of uptake, efflux and intracellular sequestration or compartmentalization of essential metal ions, and is largely regulated transcriptionally by gene regulatory proteins, collectively coined metal sensor proteins (2). Metal sensor proteins directly bind a particular metal ion, or groups of metal ions that form similar coordination complexes, to the exclusion of...
all others (7); this, in turn, allows an organism to turn on or turn off the expression of specific genes in order to mount a metabolic response to either deprivation or excess of a particular metal ion in the cell.

Metal-responsive transcription factor-1 (MTF-1) is a heavy metal sensing transcriptional activator that up-regulates the expression of genes that allow an organism to mitigate zinc, cadmium and copper toxicity (8) (for reviews, see (9–13)). MTF-1 has been identified and at least partially characterized from human, mouse (14), pufferfish *Fugu rubripes* (15), zebrafish *Danio rerio* (16,17) and *Drosophila* (18). Human and mouse MTF-1 as well as the *Drosophila* homolog, termed dMTF-1, contain multiple functional domains, including a highly conserved zinc-finger domain that recognizes the cognate DNA -structure for DNA binding (26). However, substantial data support an indirect sensing model, in which MTF-1 senses Zn(II) that is mobilized by the zinc-finger domain itself (21). However, MTF-1 also harbors multiple domains for transcriptional activation (19), and short sequences that mediate intracellular trafficking into and out of the nucleus (20).

How a particular metal ion mediates MTF-1-dependent metalloregulation of gene expression is the subject of current debate (13,21); however, multiple levels of regulation clearly exist (20,22,23). Zn(II) binding to the zinc-finger domain clearly exist (20,22,23). Zn(II) binding to the zinc-finger domain clearly stabilizes an MRE-MTF-1 complex (8). MTF-1 also harbors multiple domains for transcriptional activation (19), and short sequences that mediate intracellular trafficking into and out of the nucleus (20).

MATERIALS AND METHODS

Plasmids and fly transformation

Cys-to-Ala mutations were generated using pUAST-dMTF-1 as a template by a quick change mutagenesis technique. pUAST-dMTF-1^{4C-4A}, pUAST-dMTF-1^{2C-2A} and pUAST-dMTF-1^{6C-6A} constructs were used to generate transgenic flies with P-element mediated transformation as described earlier (37).

Fly food, fly stocks and genetics

One liter of standard fly food was composed of 55 g corn, 10 g wheat, 100 g yeast, 75 g glucose, 8 g agar and 15 ml anti-fungal agent nipagin (15% in ethanol). For toxicity experiments, food was supplemented with CuSO₄ or CdCl₂ or bathocuproinedisulfonate (BCS) disodium salt hydrate (Sigma-Aldrich No. 14,662-5) to the indicated concentrations. BCS is a specific copper chelator used to deplete copper in the food. Flies were raised at 25°C and 65% humidity. *UAS-dMTF-1*, *UAS-dMTF-1^{4CA}* (*UAS-dMTF-1^{4CA}*), *UAS-dMTF-1^{2CA}* and *UAS-dMTF-1^{6CA}*) transgenes were crossed into dMTF-1^{140-1R} (dMTF-1 null allele) background respectively. The expression of the transgenes was induced by a ubiquitous Gal4 transactivator (*actin-Gal4*).
Drosophila toxicity experiments

The flies that were homozygous for dMTF-1^{140-1R} and UAS-dMTF-1 (or its derivatives) were crossed with y w::dMTF-1^{140-1R} actin-Gal4/TM6B,y+ flies on standard food or food containing copper or BCS. From the cross, two types of progeny could be obtained: Progeny (A) flies that were expressing the transgene and were dMTF-1 null mutant. Progeny (B) flies that were not expressing the transgene and contained endogenous dMTF-1. The survival index (Is) was calculated as follows: $I_s = 2A/(A + B)$.

Quantitation of MtnA and dMTF-1 transcripts in transgenic flies

To determine the level of MtnA transcripts, larvae were raised on either standard food or food containing 100 μM CuSO₄. Only third instar stage larvae were collected for analysis. Total RNA was extracted using the TRizol reagent (Life Technologies) and nuclease S1 mapping of transcripts (100 μg of total RNA) was performed as described previously (42). The gels were developed using FLA-7000 system and bands were quantified using ImageGauge software (Fuji Film). The transcripts of the endogenous actin5c gene were measured and used for normalization of MtnA transcript levels. To monitor dMTF-1 expression levels, the gut tissue was dissected from the third instar stage larvae raised on standard food. Total RNA was extracted using TRizol and first-strand cDNA synthesis was performed with 5 μg total RNA using reverse transcriptase (RT). mRNA levels were measured by quantitative (q) PCR using a SybrGreen Q-PCR reagent kit (Sigma) in combination with the MX3000P light cycler (Stratagene, Amsterdam, The Netherlands). Initial template concentrations of each sample were calculated by comparison with serial dilutions of a calibrated standard. To verify RNA integrity and equal input levels, actin mRNA was used as a reference.

Cu(I) binding experiments by absorption and luminescence spectroscopies

All Cu(I) titration samples of C-dMTF-81 were prepared anaerobically in a glovebox ([O₂] < 2 ppm) with deoxygenated buffers and solvents in 10 mM MES, 0.1 M NaCl, pH 6.3, 25°C. The samples were kept in sealed containers, including during transfer from the glovebox for characterization. Then, 500 μM Cu(I) was titrated into 800 μL of 20 μM apo-protein in anaerobic environment and the absorption was monitored over the wavelength range 200–500 nm on a Hewlett-Packard model 8452A spectrophotometer. In magfura-2 competition experiments, Zn(II) was titrated into the mixture of 15.8 μM C-dMTF-131 and 16.3 μM magfura-2 (43). For the competition experiments with BCS, 282 μM C-dMTF-81 was titrated into a mixture of 100 μM BCS and 30 μM Cu(I) and the absorption spectra recorded from 250 to 600 nm. Luminescence spectra were recorded on an ISS PC1 Photon Counting spectrofluorometer. Also, 1.0 mM Cu(I) was titrated into 1700 μL of 20 μM apo-C-dMTF-81 and the full emission spectra were collected from 400 to 800 nm with excitation at 30 nm essentially as described (44).

RESULTS

Domain structure of Drosophila MTF-1

The domain structure of D. melanogaster MTF-1 (dMTF-1) is shown in Figure 1 (18). The fundamental domains of dMTF-1 have not yet been extensively mapped and the amino acid sequence has diverged considerably from mammalian MTF-1 outside of the DNA-binding zinc finger domain (18). However, dMTF-1 contains a cluster of six cysteines within 19 consecutive amino acids (residues 547-565) that bears some...
resemblance to the Cys₄ cluster that has been functionally characterized in hMTF-1 (23). This cluster is followed by a Thr/Ser-rich domain (13 Thr/Ser in 19 residues), which is connected via a seryl-glycyl linker to a C-terminal metallothionein (MT)-like domain, which also contains several cysteines (residues 641-791). This C-terminal MT-domain bears strong resemblance to domain IV of S. pombe Pccs, a copper chaperone for copper-zinc superoxide dismutase (SOD1) which have been shown to protect S. pombe and a S. cerevisiae ace1Δ mutant strain from copper toxicity (45). To probe the copper-binding ability of the cysteine cluster (residues 547-565), we performed a functional analysis of this region of dMTF-1 both in Drosophila and in S. cerevisiae.

Transgenic flies expressing wild-type and mutant dMTF-1 genes

To investigate whether the Cys-cluster in Drosophila MTF-1 plays any role in copper homeostasis, we generated transgenic flies with constructs in which subsets of cysteines, or all of them, are substituted by alanines (Figure 1A). As mentioned, dMTF-1 mutant flies are sensitive not only to excess copper but also to copper depletion (34). This is due to the fact that dMTF-1 activates two sets of genes that are working in opposing conditions, namely, metallothioneins at high copper, and the copper importer Ctr1B at times of copper deprivation (35). The sensitivity of dMTF-1 mutants can be rescued by co-expression of wild-type dMTF-1 transgene. To examine the role of the cysteine-rich domain, we introduced the mutant constructs dMTF-1⁰C-⁰⁴A, dMTF-1⁶C-⁶⁴A or dMTF-1⁰C-⁶⁴A encoding double (C560A/C565A), quadruple (C547A/C549A/C552A/C554A) or complete (C547A/C549A/C552A/C554A/C560A/C565A) alanine substitutions (Figure 1A), into dMTF-1 mutant flies lacking endogenous dMTF-1 and tested whether these constructs could rescue the sensitivity to either copper supplementation or copper depletion. All of the three dMTF-1 derivatives are able to rescue the sensitivity to copper starvation as well as the wild-type dMTF-1 transgene (Figure 1B). This result demonstrates that the wild-type and mutant forms of dMTF-1 are expressed to similar levels since a functional dMTF-1 is required for this.

In contrast, dMTF-1¹²C-¹⁴A and dMTF-1⁴C-⁴⁴A could only partially rescue the sensitivity to copper while dMTF-1 mutant flies expressing dMTF-1⁰C-⁶⁴A failed to survive to adulthood in copper supplemented food (Figure 1B). To further understand the molecular mechanism of the copper sensitivity phenotype, we examined the expression of metallothionein A (MtnA) in flies expressing either the wild-type or mutant alleles of dMTF-1 (Figure 2A). MtnA transcript abundance was measured by quantitative S1 nuclease mapping experiments. These data show that under copper stress (100 μM), the wild-type dMTF-1 transgene strongly activates the transcription of MtnA while dMTF-1⁰C-⁶⁴A transgene is completely unable to induce MtnA transcription. Interestingly, dMTF-1⁰C-⁴⁴A and dMTF-1¹²C-¹⁴A transgenes mediate some Cu(I)-induced MtnA expression, but to a lesser extent than wild-type dMTF-1. Control experiments reveal that the wild-type and mutant dMTF-1 transgenes are expressed to similar levels in the larval gut, with the expression of the mutant dMTF-1 alleles perhaps even slightly (∼2-fold) higher; this and the fact that all transgenes equally confer resistance to copper starvation (see Figure 1B) render unlikely the possibility that the observed phenotypes could be due to insufficient expression of mutant alleles (Figure 2B). Taken together, these data show that the cysteine-rich domain of dMTF-1 is critical for copper-induced transcriptional activation but is clearly dispensable for sensing copper scarcity.
The cysteine-rich region protects *S. cerevisiae* against copper toxicity

The above results indicate that the cysteine-rich domain plays an essential role in protecting *Drosophila* from copper toxicity by mediating up-regulation of metallothionein genes. In order to assess the importance of this domain relative to other domains in dMTF-1, we have carried out a parallel experiment in a Cu-sensitive *S. cerevisiae* strain, *Dace1*, which lacks the gene for the Cu-dependent activator of CUP1, the Cu-binding yeast metallothionein (Figure 3) (38). This strain exhibits severely attenuated survival on Cu-supplemented growth media (first two rows, Figure 3). Expression of dMTF-1 reverses some of this sensitivity in a manner that absolutely requires the Cys-rich domain (rows 3–5, Figure 3). Interestingly, expression of the entire C-terminal domain of dMTF-1 (C + MT) induces resistance to Cu-toxicity equivalent to that of the MT-like domain of the Cu-chaperone pccS of *S. pombe* (45), with most of the protection mediated by the Cys-rich domain itself (rows 6–8, Figure 3).

The cysteine-rich region of dMTF-1 binds four mol•equiv of Cu(I)

We hypothesized that the direct binding of Cu(I) by the sequence encompassing residues 547-565 in dMTF-1 is the basis for copper sensing in cells. To test this, we purified three recombinant dMTF-1 fragments of 131, 81 and 51 amino acids each of which contains the Cys-rich motif, encompassing residues 499-629 (denoted C-dMTF_131), 499-579 (C-dMTF_81) and 529-579 (C-dMTF_51). C-dMTF_81 was chosen for detailed study. Cu(I) titration of C-dMTF_81 (carried out at pH 6.0, 22°C) exhibits intense metal-to-ligand charge transfer absorption (Figure 4A), indicative of coordination to Cys thiolates (44). Similar spectra were obtained for C-dMTF_131 and C-dMTF_51 as well (data not shown). The absorption spectra for C-dMTF_81 saturate at 4 mol•equiv of Cu(I) and the binding is stoichiometric (tight) under these conditions (Figure 4A). Further examination of the absorption spectra at subsaturating amounts of Cu(I) added are consistent with the formation of a single molecular species throughout the course of the titration since molar (per bound Cu(I)) absorptivity spectra of the species formed at 1:1, 2:1, 3:1 and 4:1 Cu(I):C-dMTF_81 molar ratios are identical (Figure 4B) *(vide infra)*. These spectra are virtually identical to previously published spectra of Cu₄-Ace1 (46), and are consistent with highly cooperative assembly of Cu(I)₄ polynuclear cluster in C-dMTF_81.

C-dMTF_81 also binds Zn(II) (*Kₐ ≥10¹⁰ M⁻¹*) and Cd(II) (*Kₐ ≈3 × 10⁶ M⁻¹*) to form saturating 1:1 complexes under the same solution conditions (Supplementary Figure S1). However, preincubation of C-dMTF_81 with 4 mol•equiv of Zn(II) has virtually no influence on the
Cu(I) binding titration; *i.e.*, Cu(I) still binds stoichiometrically (Supplementary Figure S2A). This suggests that the Cu₄ complex is far more thermodynamically stable than other metallated complexes of C-dMTF₈₁. Consistent with this, 30 μM C-dMTF₈₁ is capable of stripping ≥80% of the Cu(I) from 30 μM Cu(I)-(BCS)₂, the latter of which forms with an affinity constant $K_{Cu} \approx 10^{19}$ M⁻¹ (Supplementary Figure S2B). This suggests that the affinity constants for BCS and C-dMTF₈₁ may be comparable.

Anaerobic titrations like those shown in Figure 4 were also acquired using luminescence spectroscopy ($\lambda_{ex} = 300$ nm). The results of a representative titration are shown in Figure 5, with full luminescence emission spectra (Figure 5A) and a plot of the $\lambda_{em}$ vs $600$ nm vs. Cu(I):C-dMTF₈₁ molar ratio (Figure 5B) shown. These spectra reveal an intensely luminescent species that shows maximum intensity at a molar ratio of 4:1, after which point the intensity sharply decreases. These data reveal that the Cu(I) ions in the Cu₄ polynuclear cluster are significantly shielded from solvent, as has been previously observed for other polynuclear metalloregulatory clusters in *S. cerevisiae* Mac1 and Ace1 (47). Further titration beyond four mol-equiv of Cu(I) results in significant bleaching of the luminescence intensity, which is not observed in an anaerobic optical titration (Figure 2). This suggests that Cu(I) ions that are added beyond saturation induce significant reorganization in the structure, which leads to a less solvent-shielded average environment for the Cu(I) ions. Addition of greater than 4 mol-equiv of Cu(I) to apo-C-dMTF₈₁ also leads to significant degradation of the ¹H-¹⁵N HSQC spectrum (data not shown) consistent with conformational exchange broadening at greater than saturating Cu(I). These complexes may well be oligomeric in nature.

**X-ray absorption spectroscopy reveals a Cu₄S₆ polynuclear cluster**

X-ray absorption spectroscopy was carried out to structurally characterize the copper binding to C-dMTF₈₁. Figure 6A shows that the Cu K-edge near-edge spectra from Cu(I)-C-dMTF₈₁ complex prepared with 1.0 and 3.5 mol-equiv of Cu(I) are essentially identical. The peak centered at around 8983 eV, is a 1s→4p transition that is commonly used as a fingerprint for determining the coordination environment of Cu(I) compounds (48). The spectra of the Cu(I)-peptide complexes are very similar to trigonally-coordinated [Cu₄(SPh)₆]²⁻ and distinct from digonally-coordinated [Cu(SC₁₀H₁₂)₂]²⁻ (48,49) (Figure 6A), suggesting the former coordination environment in the peptide.

More structural detail is available from analysis of the Cu K-edge extended X-ray absorption fine structure (EXAFS) spectra. Figure 6B and C show the EXAFS, and corresponding Fourier transforms of the Cu(I)-C-dMTF₈₁ complexes with both 1:1 and 3.5:1 Cu:peptides, together with best fits. EXAFS curve-fitting parameters are listed in Table S1 (Supplementary Material). As with the near-edge spectra, the EXAFS of the two stoichiometries are essentially identical, and gave curve fitting analysis (discussed below) that were also very similar. Two major Fourier transform peaks are observed at ≈2.3 and ≈2.7 Å, and are attributable to Cu—S and Cu···Cu interactions, respectively. In agreement with the near-edge spectra (Figure 6A), EXAFS curve fitting indicates three Cu—S at 2.2 Å. Inclusion of lighter scatterers such as N or O resulted in unreasonably small Debye-Waller factors for Cu—S, indicating a sulfur-only Cu(SR)₃ coordination. The 2.7 Å Fourier transform peak is best fitted by including two different types of Cu···Cu interactions, with two short and one long Cu···Cu interactions at 2.70 Å and 2.82 Å, respectively for 1:1 Cu(I):C-dMTF₈₁; similar fitted parameters characterize 3.5:1 Cu(I):C-dMTF₈₁ sample as well. The overall similarity of the XAS for both Cu(I):C-dMTF₈₁ stoichiometries suggests the same Cu center structure and provides direct evidence that C-dMTF₁ binds to Cu(I) cooperatively. Based on the XAS results a Cu₄S₆ polynuclear cluster is proposed to form in Cu(I)-C-dMTF₈₁, as shown in inset of Figure 6C. MALDI-TOF mass spectroscopy...
of a 1:1 Cu(I):C-dMTF_81 mixture, i.e. identical to the
1:1 sample probed by XAS, as well as a 2:1 Cu(I):
C-dMTF_131 mixture, is consistent with this picture, and
further suggests that an intramolecular (monomolecular)
polynuclear cluster is the dominant conformer in solution
(see Supplementary Figure S3).

C-dMTF_81 binds Cu(I) in an all-or-none manner

We first performed a preliminary NMR analysis of 131, 81
and 51 residue fragments of dMTF-1 encompassing
residues 499-629 (C-dMTF_131), 499-579 (C-dMTF_81)
and 529-579 (C-dMTF_51) by acquiring 1H-15N HSQC
and 1H-{15N}heteronuclear NOE (ssNOE) spectra in the
presence and absence of Cu(I). The latter experiment
carried out with C-dMTF_81 revealed that only
\( \approx 27 \) crosspeaks were characterized by positive 1H-{15N}
ssNOE values and were significantly shifted following
the addition of 4.0 mol\( \equiv \)equiv of Cu(I). This finding is
consistent with the idea that Cu(I) folds the region
immediately around the Cys cluster with little
additional long-range folding evident in these spectra (Supplementary Figures S4-S5); in the absence of Cu(I),
all resolvable crosspeaks have strongly negative ssNOE
values revealing little or no stable structure in the absence
of Cu(I) (spectra not shown). Further evidence for limited
and localized Cu-dependent folding is that amide reso-
nances that shift upon addition of Cu(I) have virtually
identical chemical shifts in the context of a fusion
protein in which 27-residues of dMTF-1 (542-568) are
C-terminally appended to protein G B1 domain (GB1)
spectra not shown) (50).

We next used NMR spectroscopy to investigate the
cooperativity of Cu 4 cluster formation by acquiring
1H-15N HSQC spectra as a function of Cu(I):C-
dMTF_81 molar ratio (Figure 7). These spectra reveal
that at subsaturating Cu(I), the spectrum corresponds
to a superposition of apo- and Cu 4 conformers with no
evidence of a non-native structural intermediate.
Quantitation of the crosspeak intensities of selected
resonances (Supplementary Figure S6) as a function of
Cu(I) loading is fully compatible with scenario, i.e. the
intensity of apo-C-dMTF_81 crosspeaks decrease mono-
tonically as Cu 4 crosspeak areas increase. The assembly of
the Cu 4 cluster is therefore highly cooperative, a result
consistent with the findings by XAS and mass spectro-
metry, which reveal significant Cu 4 polynuclear cluster
upon addition of sub-stoichiometric Cu(I). Despite the
highly cooperative Cu-binding by C_dMTF_81, the pep-
tide is characterized by a high degree of internal dynamics,
a characteristic not unprecedented from previous studies
of Cu- and Zn/Cd-loaded metallothioneins (51).
DISCUSSION

MTF-1 of *Drosophila* is capable of activating the transcription of distinct metallothionein genes (*MtnA-D*) in response to several metal ions, including Cu(I), Cd(II) and Zn(II). A recent characterization of transgenic flies carrying deletions of one of the four *Mtn* genes reveals that *MtnA* (the expression of which is studied here) is primarily responsible for protecting flies against exogenous copper load, while *MtnB-C0* flies are most sensitive to cadmium toxicity. The biological roles of *MtnC* and *MtnD*, which are closely related to *MtnB*, remain enigmatic since flies harboring a deletion of one or both of these genes exhibit near wild-type resistance against Cu and Cd toxicity (37). Binding studies revealed that *MtnA* is most strongly stabilized by Cu(I) binding, while *MtnB* binds Cd(II) preferentially over Zn(II) and Cu(I). These findings are generally consistent with the characteristics of flies harboring a metallothionein gene family knockout; these flies are viable and develop normally on standard food, but are highly sensitive to copper and cadmium toxicity. In particular, these experiments establish that *MtnA* and its regulator MTF-1 are responsible for the intense orange copper-mediated luminescence (when excited in the ultraviolet; see Figure 5) associated with specialized cells from the intestinal tract, termed midgut ‘copper cells’ (36). These cells likely function as storage depots for excess Cu(I), essentially protecting the organism against the effects of Cu(I)-mediated oxidative stress as well as a source of intracellular copper under conditions of copper deprivation (35). Interestingly, in contrast to mammalian MTF-1, *Drosophila* metallothioneins appear to play only a minor role against zinc toxicity (36). On the other hand, the expression of the zinc efflux transporter ZnT35C, thought to be analogous to the mammalian zinc exporter ZnT1, is strongly induced by Zn in an MTF-1-dependent manner (52).

How a single transcriptional activator, dMTF-1, is capable of up-regulating the expression of specific genes in response to distinct metal ions is unclear. One plausible scenario is that the metal selectivity of gene expression is dictated by the promoter-specific nature of the protein complex containing MTF-1 that mediates a specific transcriptional response. There is some evidence in support of this idea, since when MREs are excised from their context in the *Ctr1B* promoter (which is induced by Cu-scarcity) and placed in a non-native, mini-promoter context, they simply function as activating elements in response to copper overload, just like those derived from metallothionein genes (which are activated upon Cu-overload) (34). Along this vein of thought, MTF-1 might function as a promoter-specific adaptor molecule, in which the Zn(II)-bound zinc fingers mediate a direct interaction with the MRE, and another domain of the molecule mediates a Cu- or Cd- or Zn-specific complex with a putative co-activator or co-repressor. The foundational tenet of this hypothesis is that MTF-1 should be capable of forming complexes with Cu or Cd/Zn, with the distinct structures of each coordination complex (Cu vs. Zn/Cd) required to mediate metal-specific protein-protein interactions.

In the work presented here, we show that a C-terminal Cys-cluster of dMTF-1 encompassing six closely spaced cysteines forms a very stable, highly cooperative brightly luminescent Cu₄S₆ polynuclear cluster. This cluster is essential for dMTF-1 to drive the expression of its target genes.
gene MtnA, because a complete Cys substitution (6C-6A) in dMTF-1 abolishes its activity under copper stress and keeps the MtnA gene uninduced. Such a defect at molecular level results in a copper sensitive phenotype of mutant Drosophila. Partial alanine substitution of two (2C-2A) or four (4C-4A) of the Cu(I)-liganding cysteines also results in a severely attenuated survival index; this suggests that formation of the Cu_{L6} (L = ligand) complex optimally protects flies against copper toxicity by inducing MtnA expression. This short 19-amino acid domain is necessary and sufficient to bind four mole equiv of Cu tightly and stoichiometrically in vitro and in vivo, the latter measured by examining the viability of Cu-sensitive S. cerevisiae strain on Cu-supplemented media.

Strikingly, the cysteine-rich domain of dMTF-1 is reminiscent of Cu-sensing domains of other Cu-regulators from lower eukaryotes, including Mac1 and Ace1 from S. cerevisiae, Cuf1 from the fission yeast S. pombe (40), GRIGEA from Podospora anserina (39), and Amt1 from Candida glabrata (41), in the complete absence of amino acid sequence homology. Spectroscopic studies of Amt1, Mac and Ace1 reveal that each forms intensely luminescent tetracysteine Cu_{L6} ‘cage-like’ clusters containing trigonally coordinated solvent-shielded Cu(I) ions, with significant Cu-Cu interactions, that either stimulate (Ace1, Amt1) or inhibit (Mac1) promoter DNA binding and/or transcriptional activation (41,47). A characteristic feature of the Cu complexes formed by Amt1, Ace and Mac1 is a short 2.7 Å Cu-Cu distance, also found here for dMTF-1 (41,47). Extensive molecular genetic studies have been carried out on S. cerevisiae Mac1, and these experiments are consistent with a model in which the Cu-binding domain forms a direct intramolecular protein–protein interaction with the N-terminal DNA-binding and nearby transactivation domain that allosterically blocks Mac1 function at multiple levels (53–55). Since Mac1 regulates the expression of the two high affinity Cu-importers CTR1 and CTR3, Cu-replete cells turn off the transcriptional activity of Mac1 in a Cu-dependent manner. In contrast, Cu-binding to both Ace1 and Amt1 strongly activates binding to the CuREs (copper response element) that either stimulate (Ace1, Amt1) or inhibit (Mac1) promoter DNA binding and/or transcriptional activation of Mac1 in a Cu-dependent manner. In contrast, Cu-binding to both Ace1 and Amt1 strongly activates binding to the CuREs (copper response elements) positioned upstream of the genes encoding two metallothioneins, CUP1 and CRS3, and superoxide dismutase SOD1. It seems plausible that Cu-binding to the C-terminal domain in dMTF-1 might unmask a critical transcription activation domain that allows the recruitment of TFIIId to the promoter (32) or perhaps the chromatin remodeling enzymes, Swi5/Snf and Gen5, as has been demonstrated for C. glabrata Amt1 (56).

The Cu-regulatory complexes formed by dMTF-1 and yeast transcriptional activators contrast sharply with those found in known copper metalloregulatory proteins in prokaryotes, which form either digonal (57), mononuclear trigonal planar (44), or binuclear Cu_{S2} coordination complexes (2,58). Unlike each of these systems which are highly specific for Cu(I) (and its structural surrogate Ag(I)) (46), the intrinsic metal specificity of the metal sensing domain of dMTF-1 may well be relaxed since dMTF-1 has to bind and metalloregulate gene expression from a variety of promoters in response to a number of different metal ions, including Cd(II) and Zn(II). A direct role of the Cys-cluster in sensing both Cd(II) and Zn(II) would require that the Cys-cluster of dMTF-1 bind these metal ions as well. In fact, the Cys cluster in dMTF-1 forms stoichiometric 1:1 complexes with both Cd(II) and Zn(II), rather than a polynuclear cluster; however, Cu(I) easily outcompetes Zn(II), with Zn(II) binding considerably more tightly than Cd(II) (Supplementary Figure S1).

Figure 8. Cysteine clusters of metalloregulatory transcription factors. (A) Conservation of the Cys-rich region in MTF-1 of Drosophila and a mosquito. Dm, Drosophila melanogaster; Dps, Drosophila pseudoobscura; Dmo, Drosophila mojavensis; Dgr, Drosophila griseum; An, Anopheles gambiae (23). (B) MTF-1s of yeasts and a filamentous fungus (39,40,47). Mac1 and Cuf1, copper-regulated transcription factors of baker’s yeast (S. cerevisiae) and fission yeast (S. pombe), respectively. Grisea, copper-responsive transcription factor of the fungus Podospora anserina. (C) Tetracysteine cluster of human and mouse MTF-1, required for transcriptional response to zinc and cadmium load (9,23).
Ongoing studies in our laboratories are directed toward understanding the molecular mechanism of differential sensing and regulation performed by MTF-1 in response to a variety of inducers.

**SUPPLEMENTARY DATA**
Supplementary Data are available at NAR Online.

**ACKNOWLEDGEMENTS**
We thank Simon Labbé, University of Sherbrooke, for the gift of plasmids p426GPD and p426GPD-pccs-IV and Dennis Thiele, Duke University, for the *S. cerevisiae* strains used here. We also thank Viola Günther for communicating unpublished data. We thank Jon Karty and Zhen Ma, Indiana University, for their help in acquiring the mass spectrometry data. This work was supported by grants from the US National Institutes of Health (GM042569) and the Robert A. Welch Foundation (A-1295) to D.P.G., and the Swiss National Science Foundation (3100-064139), the Kanton Zurich, and the European Union (GENINTEG project ‘Mechanisms of Gene Integration’ LSHG-CT-2003-503303) to W.S. Work at the University of Saskatchewan was supported by a Canada Research Chair to W.S. Portions of this work were carried out at the Stanford Synchrotron Radiation Laboratory which is funded by the US Department of Energy with additional support from the US National Institutes of Health, the Engineering Research Council (Canada), and the Canadian Institute for Health Research. Open Access charges for this article were waived by Oxford University Press.
