Task-specific motor rehabilitation therapy after stroke improves performance in a different motor task: translational evidence

El Amki, M ; Baumgartner, P ; Bracko, O ; Luft, A R ; Wegener, S

Abstract: While the stroke survivor with a motor deficit strives for recovery of all aspects of daily life movements, neurorehabilitation training is often task specific and does not generalize to movements other than the ones trained. In rodent models of post-stroke recovery, this problem is poorly investigated as the training task is often the same as the one that measures motor function. The present study investigated whether motor training by pellet reaching translates into enhancement of different motor functions in rats after stroke. Adult rats were subjected to 60-min middle cerebral artery occlusion (MCAO). Five days after stroke, animals received either training consisting of 7 days of pellet reaching with the affected forelimb (n = 18) or no training (n = 18). Sensorimotor deficits were assessed using the sticky tape test and a composite neuroscore. Infarct volumes were measured by T2-weighted MRI on day 28. Both groups of rats showed similar lesion volume and forelimb impairment after stroke. Trained animals improved in the sticky tape test after day 7 post-stroke reaching peak performance on day 14. More reaching attempts during rehabilitation were associated with a better performance in the sticky tape removal time. Task-oriented motor training generalizes to other motor functions after experimental stroke. Training intensity correlates with recovery.

Abstract

Background and Purpose: While the stroke survivor with a motor deficit strives for recovery of all aspects of daily life movements, neurorehabilitation training is often task specific and does not generalize to movements other than the ones trained. In rodent models of post-stroke recovery, this problem is poorly investigated as the training task is often the same as the one that measures motor function. The present study investigated whether motor training by pellet reaching translates into enhancement of different motor functions in rats after stroke.

Methods: Adult rats were subjected to 60 min middle cerebral artery occlusion (MCAO). Five days after stroke, animals received either training consisting of 7 days of pellet reaching with the affected forelimb (n = 18) or no training (n = 18). Sensorimotor deficits were assessed using the sticky tape test and a composite neuroscore. Infarct volumes were measured by T2-weighted MRI on day 28.

Results: Both groups of rats showed similar lesion volume and forelimb impairment after stroke. Trained animals improved in the sticky tape test after day 7 post stroke reaching peak performance on day 14. More reaching attempts during rehabilitation were associated with a better performance in the sticky tape removal time.

Conclusions: Task-oriented motor training generalizes to other motor functions after experimental stroke. Training intensity correlates with recovery.

Introduction

About 60 % of stroke survivors suffer from motor disability 6 months after stroke [1,2]. By training of motor skills, rehabilitation aims to maximize patients' functional independence and quality of life. The physiological mechanisms of training interventions are incompletely understood, especially their generalization, i.e., how and how much improvement in the specific task trained generalizes to other movements. These mechanisms need to be explored in animal models to optimize and develop treatments.

In rodents, post-stroke motor rehabilitation by pellet reaching training improves pellet reaching success [3]. This is accompanied by reorganization in motor cortex regions controlling the affected limb [4], e.g., an increase in dendritic complexity [5,6]. The issue of generalization of trained to other tasks has not been addressed in animal models of post-stroke recovery.

The present study investigated whether motor training by pellet reaching translates into improvement in other motor tasks in a rat stroke model. The transient MCAO was chosen for stroke induction, because the lesion is not confined to the motor cortex but has a variable spread towards adjacent cortical and subcortical areas, similar to human stroke.

Materials and Methods

All experiments were performed in accordance with the guidelines and regulations approved by the Federal Veterinary Office of Switzerland (Veterinary Office of the Canton of Zurich). Adult male Sprague Dawley rats (280 to 310 mg body weight) were used. The experimental setup is shown in figure 1. Out of 46 animals, 5 animals died or had to be euthanized prematurely due to massive infarction. Five rats were excluded because of insufficient stroke induction as judged by less than 15 seconds to remove the sticky tape on day 1 after MCAO. Analysis of sensorimotor scores and stroke lesion size was performed by an investigator blinded to group assignment.

Middle cerebral artery occlusion (MCAO)

During surgery, rats were anesthetized using facemask inhalation of 1.5 to 2.5% isoflurane in a 2:1 N₂O:O₂ atmosphere. Animals were subjected to 60 minutes MCAO as described previously [7]. Laser Doppler flowmetry (Moor Instruments Ltd, Millwey, UK) was used to confirm the occlusion of the MCA. The probe was fixed on the skull in the left MCA territory and rats with less than 30% drop in cerebral blood flow were excluded from the studies. The body temperature was monitored throughout surgery using a rectal probe and maintained at 37°C with a normothermic blanket (Harvard apparatus, Edenbridge, Kent., UK).

Pre-training, motor skill learning and motor rehabilitation

Training procedures were conducted as previously described [8]. More details are available as supplemental data. One daily session consisting of 100 trials or a maximum time of 45 minutes was performed for each animal. Reaching performance was measured by counting the number of successful reaches.

Animals were randomized into the rehabilitation (“rehab”) or no rehabilitation (“no rehab”) group on day 4 after MCAO. Five days after MCAO (D5), animals of the rehab group received daily pellet reaching sessions for 7 days until D12. The number of successful reaches was tested in all animals at D5 and D12 after MCAO.

Sensorimotor testing

Sensorimotor function was evaluated using the adhesive tape removal test as well as a composite observational neurological score (see supplemental methods) [7].

Magnetic Resonance Imaging Methods (MRI)

On day 28 after MCAO, MRI was carried out on a 4.7T rodent scanner (see also supplemental material).

Statistical analysis

A sample size calculation (alpha 0.05, power 0.8) was performed based on previous sticky tape removal test data in rats after MCAO. We calculated a minimum sample size of 16 animals per group to show an effect size of 0.9. Power calculation was performed using G Power Software (version 3.1.5). Statistical analyses were done using SPSS v12.0 for Windows. All values are given as mean \pm standard error of mean (s.e.m.). For group comparisons, either the two-sided independent sample t-test or the nonparametric Mann–Whitney U test was used depending on data distribution. A p-value <0.05 was considered significant.

Results

Before stroke surgery, both groups achieved a similar reaching performance ($38.1 \pm 7.1\%$ success rate for rehab *versus* $32.5 \pm 6.2\%$ for no rehab, Figure 2A). Five days after stroke, all animals had considerable problems in obtaining pellets with the impaired limb ($2.1 \pm 1.0\%$ in rehab and $2.0 \pm 0.9\%$ in no rehab group,). As expected, animals that received daily rehabilitation from D5 to D12 after MCAO achieved a higher pellet reaching success rate at D12 ($23.0 \pm 5.5\%$ *versus* $4.2 \pm 2.6\%$ $p < 0.01$; Figure 2A). MRI stroke lesion analysis showed no difference between the two groups ($165 \pm 41.9\text{mm}^3$ in rehab *versus* $176 \pm 38.7\text{mm}^3$ in no rehab animals). In the composite neurological score, trained and control animals were similarly affected after stroke (Figure 2B). In the sticky tape test, deficits to perceive and remove the tape on the right side were noted in all animals at D1 after MCAO (Figure 2C). However, animals with rehabilitation performed faster in the sticky tape removal task (motor component) on D14 than animals without rehabilitation ($12 \pm 2.6\text{s}$ *versus* $38 \pm 10.2\text{s}$; $p = 0.007$). A high cumulative number of pellet reaches during training was negatively correlated with the time to remove the sticky tape on D14 ($R = -0.68$, $P < 0.01$, Figure 2D).

Discussion

Although intense rehabilitation incorporating exercise, forelimb constraint therapy and task specific pellet reaching has been shown to enhance performance in a similar, but not identical task-specific test (tray-reaching) in rats after brain injury, our study demonstrates that a task-oriented motor rehabilitation algorithm alone can improve motor function in a task that is substantially different from the trained one [9]. Daily pellet reaching training enhanced motor ability for sticky tape removal.

Motor rehabilitation by pellet reaching training is focused on recovery of highly specific functions (skilled grasping ability) and requires intensive training and practice of the impaired function [10]. As potential mechanisms mediating the beneficial effects of motor rehabilitation, pro-plastic and neurotrophic factors such as brain derived neurotrophic factor (BDNF) and insulin-like growth factor (IGF-1) have been indicated [11]. The control group did not show significant recovery in the skilled reaching task. Neither the sensory component of the sticky tape test, nor the composite neurologic score were influenced by motor rehabilitation in our model. This argues for specific effects on motor recovery and against other functional domains, such as sensation or neglect involved in the observed regain of function.

The improvement in sticky tape removal was correlated with more successful pellet reaching attempts, indicating that a higher intensity of training may be beneficial. Since the effect was most pronounced on day 14 and less evident on day 28, our experimental data argue for continued motor rehabilitation for stroke patients in order to maintain a sustained effect on motor function.

Summary

Although studies generally support the concept that motor rehabilitation is associated with improved outcomes after stroke, few experimental studies have specifically tested whether focused rehabilitation improves other motor outcomes. To our knowledge, our study represents the first translational evidence that task specific training after stroke generalizes to a different motor task.
