The Environment and Directed Technical Change*

Daron Acemoglu[†] Philippe Aghion[‡] Leonardo Bursztyn[§] David Hemous[¶]

April 28, 2010

Abstract

This paper introduces endogenous and directed technical change in a growth model with environmental constraints. A unique final good is produced by combining inputs from two sectors. One of these sectors uses “dirty” machines and thus creates environmental degradation. Research can be directed to improving the technology of machines in either sector. We characterize dynamic tax policies that achieve sustainable growth or maximize intertemporal welfare. We show that: (i) in the case where the inputs are sufficiently substitutable, sustainable long-run growth can be achieved with temporary taxation of dirty innovation and production; (ii) optimal policy involves both “carbon taxes” and research subsidies, so that excessive use of carbon taxes is avoided; (iii) delay in intervention is costly: the sooner and the stronger is the policy response, the shorter is the slow growth transition phase; (iv) the use of an exhaustible resource in dirty input production helps the switch to clean innovation under *laissez-faire* when the two inputs are substitutes. Under reasonable parameter values and with sufficient substitutability between inputs, it is optimal to redirect technical change towards clean technologies immediately and optimal environmental regulation need not reduce long-run growth.

JEL Classification: O30, O31, O33, C65.

Keywords: environment, exhaustible resources, directed technological change, innovation.

1 Introduction

How to control and limit climate change caused by our growing consumption of fossil fuels and to develop alternative energy sources to these fossil fuels are among the most pressing policy challenges facing the world today.¹ While a large part of the discussion among climate scientists focuses on the effect of various policies on the development of alternative—and more “environmentally friendly”—energy sources, the response of technological change to environmental policy has until very recently been all but ignored by leading economic analyses of environment policy, which have mostly focused on computable general equilibrium models with exogenous technology.² This omission is despite the fact that existing empirical evidence indicates that changes in the relative price of energy inputs have an important effect on the types of technologies that are developed and adopted. For example, Newell, Jaffe and Stavins (1999) show that when energy prices were stable, innovations in air-conditioning reduced the prices faced by consumers, but following the oil price hikes, air-conditioners became more energy efficient. Popp (2002) provides more systematic evidence on the same point by using patent data from 1970 to 1994; he documents the impact of energy prices on patents for energy-saving innovations.

A satisfactory framework for the study of the costs and benefits of different environmental policies must therefore include at its centerpiece the endogenous response of different types of technologies to proposed policies. Our purpose is to take a first step towards the development of such a framework. We propose a simple two-sector model of directed technical change. The unique final good is produced by combining the inputs produced by these two sectors. One of them uses “dirty” machines and creates environmental degradation. Profit-maximizing researchers build on previous innovations (“build on the shoulders of giants”) and direct their research to improving the quality of machines in one or the other sector.

Our framework highlights the central roles played by the *market size* and the *price effects* on the direction of technical change (Acemoglu, 1998, 2002). The market size effect encourages innovation towards the larger input sector, while the price effect directs innovation towards the sector with higher price. The relative magnitudes of these effects are, in turn, determined by three factors: (1) the elasticity of substitution between the two sectors; (2) the relative levels of development of the technologies of the two sectors; (3) whether dirty inputs are produced using an exhaustible resource. Because of the environmental externality, the decentralized equilibrium is not optimal. Moreover, the laissez-faire equilibrium typically leads to an “environmental disaster,” where the quality of the environment falls below a critical threshold.

Our main results focus on the types of policies that can prevent such disasters, the struc-

¹See, for instance, Stott et al. (2004) on the contribution of human activity to the European heatwave of 2003, Emanuel (2005) and Landsea (2005) on the increased impact and destructiveness of tropical cyclones and Atlantic hurricanes over the last decades, and Nicholls and Lowe (2006) on sea-level rise.

²See, e.g., Nordhaus (1994), MacCracken et al. (1999), Nordhaus and Boyer (2000).

ture of optimal environmental regulation and its long-run growth implications, and the costs of delay in implementing environmental regulation. Approaches based on exogenous technology lead to three different types of answers to (some of) these questions depending on their assumptions. Simplifying existing approaches and assigning colorful labels, we can summarize these as follows. The *Nordhaus* answer is that only limited and gradual interventions are necessary. Optimal regulations should only reduce long-run growth by a modest amount. The *Stern/Al Gore* answer is less optimistic. It calls for more extensive and immediate interventions, and argues that these interventions need to be in place permanently and will likely reduce long-run growth as the price for avoiding an environmental disaster. The more pessimistic *Greenpeace* answer is that essentially all growth needs to come to an end in order to save the planet.

Against this background, our analysis suggests a very different answer. In the empirically plausible case where the two sectors (clean and dirty inputs) are highly substitutable, immediate and decisive intervention is indeed necessary. Without intervention, the economy would rapidly head towards an environmental disaster, particularly because the market size effect and the initial productivity advantage of dirty inputs would direct innovation and production to that sector, contributing to environmental degradation. However, optimal environmental regulation, or even simple suboptimal policies just using carbon taxes or profit taxes/research subsidies, would be sufficient to *redirect* technical change and avoid an environmental disaster. Moreover, these policies only need to be in place for a *temporary* period, because once clean technologies are sufficiently advanced, research would be directed towards these technologies without further government intervention. Consequently, environmental goals can be achieved without permanent intervention and without sacrificing (much or any) long-run growth. While this conclusion is even more optimistic than Nordhaus's answer, as in the Stern/Al Gore or Greenpeace perspectives delay costs are significant, not simply because of the direct environmental damage, but because delay increases the technological gap between clean and dirty sectors, necessitating a more extended period of economic slowdown in the future.

Notably, our model also nests the Stern/Al Gore and Greenpeace answers. When the two sectors are substitutable but not sufficiently so, preventing an environmental disaster requires a permanent policy intervention. Finally, when the two sectors are complementary, the only way to stave off a disaster is to stop long-run growth.

A simple but important implication of our analysis is that optimal environmental regulation should always use both an input tax ("carbon tax") to control current emissions and research subsidies or profit taxes to influence the direction of research. Even though a carbon tax would by itself discourage research in the dirty sector, using this tax both to reduce current emissions and to influence the path of research would lead to excessive distortions. Instead, optimal policy relies less on a carbon tax, and even more so on direct encouragement to the development of clean technologies.

Our framework also illustrates the effects of exhaustibility of resources on the laissez-faire

equilibrium and on the structure of optimal policy. An environmental disaster is less likely when the dirty sector uses an exhaustible resource (provided that the two sectors have a high degree of substitution) because the increase in the price of the resource as it is depleted reduces its use, and this encourages research towards clean technologies. Thus, an environmental disaster could be avoided without government intervention. Nevertheless, we also show that the structure of optimal environmental regulation looks broadly similar to the case without an exhaustible resource and again relies both on carbon taxes and research subsidies.

As a first step towards a quantitative analysis of environmental policy in the presence of endogenous and directed technical change, we also perform a simple calibration exercise. We find that for high (but reasonable) elasticities of substitution between clean and dirty inputs (nonfossil and fossil fuels), the optimal policy in the presence of directed technical change involves an immediate switch of all R&D effort to clean technologies. When clean and dirty inputs are sufficiently substitutable, the structure of optimal environmental policy appears broadly robust to different values of the discount rate (which is the main source of the different conclusions in the Stern report or in Nordhaus's research).

Our paper relates to the literature on growth, resources, and the environment. Nordhaus's (1994) pioneering study proposed a dynamic integrated model of climate change and the economy (the DICE model), which extends the neoclassical Ramsey model with equations representing emissions and climate change. In our calibration exercise we build on Nordhaus's study and results. Another branch of the literature focuses on the measurement of the costs of climate change, particularly stressing issues related to risk, uncertainty and discounting.³ Based on the assessment of discounting and related issues, this literature has prescribed either decisive and immediate governmental action (e.g., Stern, 2006) or a more gradualist approach (e.g., Nordhaus, 2004), with modest control in the short-run followed by sharper emissions reduction in the medium and the long run. Recent work by Golosov et al. (2009) characterizes the structure of optimal policies in a model with exogenous technology and exhaustible resources, where oil suppliers set prices to maximize discounted profits. They show that the optimal resource tax should be decreasing over time. Finally, some authors, for example, Hepburn (2006) and Pizer (2002), have built on Weitzman's (1974) analysis on the use of price or quantity instruments to study climate change policy and the choice between taxes and quotas.

The response of technology to environmental degradation and environmental policy, our main focus in this paper, has received much less attention in the economics literature, however. Early work by Stokey (1998) highlighted the tension between growth and the environment, and showed that degradation of the environment can create an endogenous limit to growth. Aghion and Howitt (1998, Chapter 5) emphasized that environmental constraints may not prevent sustainable long-run growth when "environment-friendly" innovations are allowed.

³For example, Stern (2006), Weitzman (2007, 2009), Dasgupta (2007, 2008), Nordhaus (2007), von Below and Persson (2008), Mendelsohn (2007), and Tol and Yohe (2006).

Recent research by Jones (2009) provides a systematic analysis of conditions under which environmental and other costs of growth will outweigh its benefits. Neither of these early contributions allowed technical change to be directed to clean or dirty technologies.

Subsequent work by Popp (2004) allowed for directed innovation in the energy sector. Popp presents a calibration exercise and establishes that models that ignore the directed technical change effects can significantly overstate the cost of environmental regulation. While Popp's work is highly complementary to ours, neither his work nor others develop a systematic framework for the analysis of the impact of environmental regulations on the direction of technological change. We develop a general and tractable framework to perform systematic comparative analyses for the effects of different types of policies on innovation, growth and environmental resources, to characterize the structure of optimal regulation, and to study the implications of dirty inputs using exhaustible resources.⁴

The remainder of the paper is organized as follows. Section 2 introduces our general framework. Section 3 focuses on the case without an exhaustible resource. It shows that laissez-faire equilibrium leads to an environmental disaster. It then shows how simple policy interventions can prevent environmental disasters and clarifies the role of directed technical change in these results. Section 4 characterizes the structure of optimal environmental policy in this setup. Section 5 studies the economy with exhaustible resources. Section 6 provides a preliminary quantitative assessment of how directed technical change affects the structure of optimal policy under reasonable parameter values. Section 7 concludes. Appendix A contains the proofs of some of the key results stated in the text, while Appendix B, which is available online, contains the remaining proofs and additional quantitative exercises.

2 General Framework

We consider an infinite-horizon discrete-time economy inhabited by a continuum of households comprising workers, entrepreneurs and scientists. We assume that all households have preferences (or that the economy admits a representative household with preferences):

$$\sum_{t=0}^{\infty} \frac{1}{(1+\rho)^t} u(C_t, S_t), \quad (1)$$

where C_t is consumption of the unique final good at time t , S_t denotes the *quality of the environment* at time t , and $\rho > 0$ is the discount rate.⁵ We assume that $S_t \in [0, \bar{S}]$, where \bar{S} is

⁴First attempts at introducing endogenous directed technical change in models of growth and the environment build, as we do, on Acemoglu (1998, 2002) and include Grubler and Messner (1998), Manne and Richels (2002), Messner (1997), Buonanno et al. (2003), Nordhaus (2002), Sue Wing (2003), and Di Maria and Valente (2006). Grimaud and Rouge (2008), Gans (2009) and Aghion and Howitt (2009, Chapter 16) are more closely related to the approach followed in this paper. The early contribution by Goulder and Schneider (1999) studied the sectoral implications of CO2 abatement policies in a model with endogenous R&D.

⁵For now, S can be thought of as a measure of general environmental quality. In our quantitative exercise in Section 6, we explicitly relate S to the increase in temperature since pre-industrial times and to carbon

the quality of the environment absent any human pollution, and to simplify the notation, we also assume that this is the initial level of environmental quality, that is, $S_0 = \bar{S}$.

The instantaneous utility function $u(C, S)$ is increasing both in C and S , twice differentiable and jointly concave in (C, S) . Moreover, we impose the following Inada-type conditions:

$$\lim_{C \downarrow 0} \frac{\partial u(C, S)}{\partial C} = \infty, \lim_{S \downarrow 0} \frac{\partial u(C, S)}{\partial S} = \infty, \text{ and } \lim_{S \downarrow 0} u(C, S) = -\infty. \quad (2)$$

The last two conditions imply that the quality of the environment reaching its lower bound has severe utility consequences. Finally we assume that

$$\frac{\partial u(C, \bar{S})}{\partial S} \equiv 0, \quad (3)$$

which implies that when S reaches \bar{S} , the value of the marginal increase in environmental quality is small. This assumption is adopted to simplify the characterization of optimal environmental policy in Section 4.

There is a unique final good, produced competitively using “clean” and “dirty” inputs, Y_c and Y_d , according to the aggregate production function

$$Y_t = \left(Y_{ct}^{\frac{\varepsilon-1}{\varepsilon}} + Y_{dt}^{\frac{\varepsilon-1}{\varepsilon}} \right)^{\frac{\varepsilon}{\varepsilon-1}}, \quad (4)$$

where $\varepsilon \in (0, +\infty)$ is the elasticity of substitution between the two sectors and we suppress the distribution parameter for notational simplicity. Throughout, we say that the two sectors are (gross) *substitutes* when $\varepsilon > 1$ and (gross) *complements* when $\varepsilon < 1$ (throughout we ignore the “Cobb-Douglas” case of $\varepsilon = 1$).⁶ The case of substitutes $\varepsilon > 1$ (in fact, an elasticity of substitution significantly greater than 1) appears as the more empirically relevant benchmark, since we would expect successful clean technologies to substitute for the functions of dirty technologies. For this reason, throughout the paper we assume that $\varepsilon > 1$ unless specified otherwise (the corresponding results for the case of $\varepsilon < 1$ are discussed in subsection 3.4).

The two inputs, Y_c and Y_d , are produced using labor and a continuum of sector-specific machines (intermediates), and the production of Y_d may also use a natural exhaustible resource:

$$Y_{ct} = L_{ct}^{1-\alpha} \int_0^1 A_{cit}^{1-\alpha} x_{cit}^\alpha di \text{ and } Y_{dt} = R_t^{\alpha_2} L_{dt}^{1-\alpha} \int_0^1 A_{dit}^{1-\alpha_1} x_{dit}^{\alpha_1} di \quad (5)$$

concentration in the atmosphere.

⁶The degree of substitution, which plays a central role in the model, has a clear empirical counterpart. For example, renewable energy, provided it can be stored and transported efficiently, would be highly substitutable with energy derived from fossil fuels. This reasoning would suggest a (very) high degree of substitution between dirty and clean inputs, since the same production services can be obtained from alternative energy with less pollution. In contrast, if the “clean alternative” were to reduce our consumption of energy permanently, for example by using less effective transport technologies, this would correspond to a low degree of substitution, since greater consumption of non-energy commodities would increase the demand for energy. More generally, this parameter, though not systematically investigated by existing research, should be estimated in future empirical work and become a crucial input into the design of environmental policy.

where $\alpha, \alpha_1, \alpha_2 \in (0, 1)$, $\alpha_1 + \alpha_2 = \alpha$, A_{jit} is the quality of machine of type i used in sector $j \in \{c, d\}$ at time t , x_{jit} is the quantity of this machine and R_t is the flow consumption from an exhaustible resource at time t . The evolution of the exhaustible resource is given by the difference equation:

$$Q_{t+1} = Q_t - R_t, \quad (6)$$

where Q_t is the resource stock at date t . The per unit extraction cost for the exhaustible resource is $c(Q_t)$, where Q_t denotes the resource stock at date t , and c is a non-increasing function of Q . In Section 5, we study two alternative market structures for the exhaustible resource, one in which it is a “common resource” so that the user cost at time t is given by $c(Q_t)$, and one in which property rights to the exhaustible resource are vested with infinitely-lived firms (or consumers), in which case the user cost will be determined by the Hotelling rule. Note that the special case where $\alpha_2 = 0$ (and thus $\alpha_1 = \alpha$) corresponds to an economy without the exhaustible resource, and we will first analyze this special case.

Market clearing for labor requires labor demand to be less than total labor supply, which is normalized to 1, i.e.,

$$L_{ct} + L_{dt} \leq 1. \quad (7)$$

In line with the literature on endogenous technical change, machines (for both sectors) are supplied by monopolistically competitive firms. Regardless of the quality of machines and of the sector for which they are designed, producing one unit of any machine costs ψ units of the final good. Without loss of generality, we normalize $\psi \equiv \alpha^2$.

Market clearing for the final good implies that

$$C_t = Y_t - \psi \left(\int_0^1 x_{cit} di + \int_0^1 x_{dit} di \right) - c(Q_t)R_t. \quad (8)$$

The innovation possibilities frontier is as follows. At the beginning of every period, each scientist decides whether to direct her research to clean or dirty technology. She is then randomly allocated to at most one machine (without any congestion; so that each machine is also allocated to at most one scientist) and is successful in innovation with probability $\eta_j \in (0, 1)$ in sector $j \in \{c, d\}$, where innovation increases the quality of a machine by a factor $1 + \gamma$ (with $\gamma > 0$), that is, from A_{jit} to $(1 + \gamma)A_{jit}$. A successful scientist (who has invented a better version of machine i in sector $j \in \{c, d\}$) obtains a one-period patent and becomes the entrepreneur for the current period in the production of machine i . In sectors where innovation is not successful, monopoly rights are allocated randomly to an entrepreneur drawn from the pool of potential entrepreneurs who then use the old technology.⁷ This innovation possibilities

⁷The assumptions here are adopted to simplify the exposition and mimic the structure of equilibrium in continuous time models as in Acemoglu (2002) (see also Aghion and Howitt, 2009, for this approach). We adopt a discrete time setup throughout to simplify the analysis of dynamics. Appendix B shows that the qualitative results are identical in an alternative formulation with patents and free entry (instead of monopoly rights being allocated to entrepreneurs).

frontier where scientists can only target a sector (rather than a specific machine) ensures that scientists are allocated across the different machines in a sector.⁸ We also normalize the measure of scientists s to 1 and denote the mass of scientists working on machines in sector $j \in \{c, d\}$ at time t by s_{jt} . Market clearing for scientists then takes the form

$$s_{ct} + s_{dt} \leq 1. \quad (9)$$

Let us next define

$$A_{jt} \equiv \int_0^1 A_{jit} di \quad (10)$$

as the average productivity in sector $j \in \{c, d\}$, which implies that A_{dt} corresponds to “dirty technologies,” while A_{ct} represents “clean technologies”. The specification for the innovation possibilities frontier introduced above then implies that A_{jt} evolves over time according to the difference equation

$$A_{jt} = (1 + \gamma\eta_j s_{jt}) A_{jt-1}. \quad (11)$$

Finally, the quality of the environment, S_t , evolves according to the difference equation

$$S_{t+1} = -\xi Y_{dt} + (1 + \delta) S_t, \quad (12)$$

whenever the right hand side of (12) is in the interval $(0, \bar{S})$. Whenever the right hand side is negative, $S_{t+1} = 0$, and whenever the right hand side is greater than \bar{S} , $S_{t+1} = \bar{S}$ (or equivalently, $S_{t+1} = \max\{\min\{-\xi Y_{dt} + (1 + \delta) S_t; 0; \bar{S}\}\}$). The parameter ξ measures the rate of environmental degradation resulting from the production of dirty inputs, and δ is the rate of “environmental regeneration”. Recall also that \bar{S} is the initial and the maximum level of environmental quality corresponding to zero pollution. This equation introduces the environmental externality, which is caused by the production of the dirty input.

Equation (12) encapsulates several important features of environmental change in practice. First, the exponential regeneration rate δ captures the idea that greater environmental degradation is typically presumed to lower the regeneration capacity of the globe. For example, part of the carbon in the atmosphere is absorbed by the ice cap; as the ice cap melts because of global warming, more carbon is released into the atmosphere and the albedo of the planet

⁸As highlighted further by equation (11) below, this structure implies that innovation builds on the existing level of quality of a machine, and thus incorporates the “building on the shoulders of giants” feature. In terms of the framework in Acemoglu (2002), this implies that there is “state dependence” in the innovation possibilities frontier, in the sense that advances in one sector make future advances in that sector more profitable or more effective. This is a natural feature in the current context, since improvements in fossil fuel technology should not (and in practice do not) directly translate into innovations in alternative and renewable energy sources. Nevertheless, one could allow some spillovers between the two sectors, that is, “limited state dependence” as in Acemoglu (2002). In particular, in the current context, we could adopt a more general formulation which would replace the key equation (11) below by $A_{jt} = (1 + \gamma\eta_j s_{jt}) \phi_j(A_{jt-1}, A_{\sim jt-1})$, for $j \in \{c, d\}$, where $\sim j$ denotes the other sector and ϕ_j is a linearly homogeneous function. Our qualitative results continue to hold provided that $\phi_c(A_c, A_d)$ has an elasticity of substitution greater than one as $A_c/A_d \rightarrow \infty$ (since in this case ϕ_c becomes effectively linear in A_c in the limit where innovation is directed at clean technologies).

is reduced, further contributing to global warming. Similarly, the depletion of forests reduces carbon absorption, also contributing to global warming. Second, the upper bound \bar{S} captures the idea that environmental degradation results from pollution, and that pollution cannot be negative. We discuss below how our results change under alternative laws of motion for the quality of the environment.

Equation (12) also incorporates, in a simple way, the major concern of the majority of climate scientists, that the environment may deteriorate so much as to reach a “point of no return”. In particular, if $S_t = 0$, then S_τ will remain at 0 for all $\tau > t$. Our assumption that $\lim_{S \downarrow 0} u(C, S) = -\infty$ implies that $S_t = 0$ for any finite t cannot be part of a welfare-maximizing allocation (for any $\rho < \infty$). Motivated by this feature, we define the notion of an *environmental disaster*, which will be useful for developing the main intuitions of our model.

Definition 1 *An environmental disaster occurs if $S_t = 0$ for some $t < \infty$.*

3 Environmental Disaster without Exhaustible Resources

In this and the next section, we focus on the case with $\alpha_2 = 0$ (and thus $\alpha_1 = \alpha$), where the production of the dirty input does not use the exhaustible resource. This case is of interest for several reasons. First, because the production technologies of clean and dirty inputs are symmetric in this case, the effects of directed technical change can be seen more transparently. Second, we believe that this case is of considerable empirical relevance, since the issue of exhaustibility appears secondary in several activities contributing to climate change, including deforestation and power generation using coal (where the exhaustibility constraint is unlikely to be binding for a long time). We return to the more general case where $\alpha_2 \neq 0$ in Section 5.

3.1 The *laissez-faire* equilibrium

In this subsection we characterize the *laissez-faire equilibrium* outcome, that is, the decentralized equilibrium without any policy intervention. We first characterize the equilibrium production and labor decisions for given productivity parameters. We then analyze the direction of technical change.

An *equilibrium* is given by sequences of wages (w_t), prices for inputs (p_{jt}), prices for machines (p_{jit}), demands for machines (x_{jit}), demands for inputs (Y_{jt}), labor demands (L_{jt}) by input producers $j \in \{c, d\}$, research allocations (s_{dt}, s_{ct}), and quality of environment (S_t) such that, in each period t : (i) (p_{jit}, x_{jit}) maximizes profits by the producer of machine i in sector j ; (ii) L_{jt} maximizes profits by producers of input j ; (iii) Y_{jt} maximizes the profits of final good producers; (iv) (s_{dt}, s_{ct}) maximizes the expected profit of a researcher at date t ; (v) the wage w_t and the prices p_{jt} clear the labor and input markets respectively; and (vi) the evolution of S_t is given by (12).

To simplify the notation, we define $\varphi \equiv (1 - \alpha)(1 - \varepsilon)$ and impose the following assumption, which is adopted throughout the text (often without explicitly specifying it).

Assumption 1

$$\frac{A_{c0}}{A_{d0}} < \min \left((1 + \gamma\eta_c)^{-\frac{\varphi+1}{\varphi}} \left(\frac{\eta_c}{\eta_d} \right)^{\frac{1}{\varphi}}, (1 + \gamma\eta_d)^{\frac{\varphi+1}{\varphi}} \left(\frac{\eta_c}{\eta_d} \right)^{\frac{1}{\varphi}} \right).$$

This assumption imposes the reasonable condition that initially the clean sector is sufficiently backward relative to the dirty (fossil fuel) sector that under laissez-faire the economy starts innovating in the dirty sector. This assumption enables us to focus on the more relevant part of the parameter space (Appendix A provides the general characterization).

We first consider the equilibrium at time t for given technology levels A_{cit} and A_{dit} . As the final good is produced competitively, the relative price of the two inputs satisfies

$$\frac{p_{ct}}{p_{dt}} = \left(\frac{Y_{ct}}{Y_{dt}} \right)^{-\frac{1}{\varepsilon}}. \quad (13)$$

This equation implies that the relative price of clean inputs (compared to dirty inputs) is decreasing in their relative supply, and moreover, that the elasticity of the relative price response is the inverse of the elasticity of substitution between the two inputs. We normalize the price of the final good at each date to one, i.e.,

$$(p_{ct}^{1-\varepsilon} + p_{dt}^{1-\varepsilon})^{1/(1-\varepsilon)} = 1. \quad (14)$$

To determine the evolution of average productivities in the two sectors, we need to characterize the profitability of research in these sectors, which will determine the direction of technical change. The equilibrium profits of machine producers endowed with technology A_{jit} can be written as (see Appendix A):

$$\pi_{jit} = (1 - \alpha) \alpha p_{jt}^{\frac{1}{1-\alpha}} L_{jt} A_{jit}. \quad (15)$$

Taking into account the probability of success and using the definition of average productivity in (10), the expected profit Π_{jt} for a scientist engaging in research in sector j at time t is therefore:

$$\Pi_{jt} = \eta_j (1 + \gamma) (1 - \alpha) \alpha p_{jt}^{\frac{1}{1-\alpha}} L_{jt} A_{jt-1}, \quad (16)$$

where the second line simply uses (10). Consequently, the relative benefit from undertaking research in sector c relative to sector d is governed by the ratio:

$$\frac{\Pi_{ct}}{\Pi_{dt}} = \frac{\eta_c}{\eta_d} \times \underbrace{\left(\frac{p_{ct}}{p_{dt}} \right)^{\frac{1}{1-\alpha}}}_{\text{price effect}} \times \underbrace{\frac{L_{ct}}{L_{dt}}}_{\text{market size effect}} \times \underbrace{\frac{A_{ct-1}}{A_{dt-1}}}_{\text{direct productivity effect}}. \quad (17)$$

The higher this ratio, the more profitable is R&D directed towards the clean technologies. This equation shows that incentives to innovate in the clean versus the dirty sector machines are shaped by three forces: (i) the *direct productivity effect* (captured by the term A_{ct-1}/A_{dt-1}), which pushes towards innovating in the sector with higher productivity; this force results from the presence of the “building on the shoulders of giants” effect highlighted in (11); (ii) the *price effect* (captured by the term $(p_{ct}/p_{dt})^{\frac{1}{1-\alpha}}$), encouraging innovation towards the sector with higher prices, which is naturally the relatively backward sector; (iii) the *market size effect* (captured by the term L_{ct}/L_{dt}), encouraging innovation in the sector with greater employment, and thus with the larger market for machines—when the two inputs are substitutes ($\varepsilon > 1$), this is also the sector with the higher aggregate productivity. Appendix A develops these effects more formally and also shows that in equilibrium, equation (17) can be written as:

$$\frac{\Pi_{ct}}{\Pi_{dt}} = \frac{\eta_c}{\eta_d} \left(\frac{1 + \gamma\eta_c s_{ct}}{1 + \gamma\eta_d s_{dt}} \right)^{-\varphi-1} \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^{-\varphi}. \quad (18)$$

The next lemma then directly follows from (18).

Lemma 1 *Under laissez-faire it is an equilibrium for innovation at time t to occur in the clean sector only when $\eta_c A_{ct-1}^{-\varphi} > \eta_d (1 + \gamma\eta_c)^{\varphi+1} A_{dt-1}^{-\varphi}$, in the dirty sector only when $\eta_c (1 + \gamma\eta_d)^{\varphi+1} A_{ct-1}^{-\varphi} < \eta_d A_{dt-1}^{-\varphi}$, and in both sectors when $\eta_c (1 + \gamma\eta_d s_{dt})^{\varphi+1} A_{ct-1}^{-\varphi} = \eta_d (1 + \gamma\eta_c s_{ct})^{\varphi+1} A_{dt-1}^{-\varphi}$ (with $s_{ct} + s_{dt} = 1$).*

Proof. See Appendix A. ■

The noteworthy conclusion of this lemma is that innovation will favor the more advanced sector when $\varepsilon > 1$ (which, in (18), corresponds to $\varphi \equiv (1 - \alpha)(1 - \varepsilon) < 0$).

Finally, output of the two inputs and the final good in the laissez-faire equilibrium can be written as:

$$Y_{ct} = (A_{ct}^{\varphi} + A_{dt}^{\varphi})^{-\frac{\alpha+\varphi}{\varphi}} A_{ct} A_{dt}^{\alpha+\varphi}, \quad Y_{dt} = (A_{ct}^{\varphi} + A_{dt}^{\varphi})^{-\frac{\alpha+\varphi}{\varphi}} A_{ct}^{\alpha+\varphi} A_{dt}, \quad (19)$$

$$\text{and } Y_t = (A_{ct}^{\varphi} + A_{dt}^{\varphi})^{-\frac{1}{\varphi}} A_{ct} A_{dt}.$$

Using these expressions and Lemma 1, we establish:

Proposition 1 *Suppose that $\varepsilon > 1$ and Assumption 1 holds. Then there exists a unique laissez-faire equilibrium where innovation always occurs in the dirty sector only, and the long-run growth rate of dirty input production is $\gamma\eta_d$.*

Proof. See Appendix A. ■

Since the two inputs are substitutes ($\varepsilon > 1$), innovation starts in the dirty sector, which is more advanced initially (Assumption 1). This increases the gap between the dirty and the clean sectors and the initial pattern of equilibrium is reinforced: only A_d grows (at the rate $\gamma\eta_d > 0$) and A_c remains constant. Moreover, since φ is negative in this case, (19) implies that in the long run Y_d also grows at the rate $\gamma\eta_d$.

3.2 Directed technical change and environmental disaster

In this subsection, we show that the laissez-faire equilibrium leads to an environmental disaster and illustrate how a simple policy of “redirecting technical change” can avoid this outcome.

The result that the economy under laissez-faire will lead to an environmental disaster follows immediately from the facts that dirty input production Y_d always grows without bound (Proposition 1) and that a level of production of dirty input greater than $(1 + \delta)\xi^{-1}\bar{S}$ necessarily leads to a disaster next period. We thus have (proof omitted):

Proposition 2 *Suppose that $\varepsilon > 1$ and Assumption 1 holds. Then the laissez-faire equilibrium always leads to an environmental disaster.*

Remark 1 Our exposition may give the impression that dirty and clean technologies are entirely separated. In practice, clean innovation may also reduce the environmental degradation resulting from (partially) dirty technologies. In fact, our model implicitly allows for this possibility. In particular, our model is equivalent to a formulation where there are no clean and dirty inputs, and instead, the unique final good is produced according to the technology

$$Y_t = \left(\left(L_{ct}^{1-\alpha} \int_0^1 A_{cit}^{1-\alpha} x_{cit}^\alpha di \right)^{\frac{\varepsilon-1}{\varepsilon}} + \left(R_t^{\alpha_2} L_{dt}^{1-\alpha} \int_0^1 A_{dit}^{1-\alpha_1} x_{dit}^{\alpha_1} di \right)^{\frac{\varepsilon-1}{\varepsilon}} \right)^{\frac{\varepsilon}{\varepsilon-1}}, \quad (20)$$

where A_{ct} and A_{dt} correspond to the fraction of “tasks” performed using clean versus dirty technologies, and the law of motion of the environmental stock takes the form

$$S_{t+1} = -\xi \times (Y_{dt}/Y_t) \times Y_t + (1 + \delta) S_t,$$

where Y_{dt}/Y_t measures the extent to which overall production uses dirty tasks. Clean innovation, increasing A_{ct} , then amounts to reducing the pollution intensity of the overall production process. This emphasizes that our model equivalently captures technical change that reduces the pollution from existing production processes. In addition, our main results can be easily extended to several more general formulations; for example, $S_{t+1} = -f(Y_{dt}/Y_t) \times Y_t + (1 + \delta) S_t$, or $S_{t+1} = -f\left(\left(\int_0^1 x_{dit} di\right)/Y_t\right) \times Y_t + (1 + \delta) S_t$, where $\left(\int_0^1 x_{dit} di\right)/Y_t$ denotes the quantity of dirty machines used per unit of final good production, and f is a continuously increasing function with $f(0) = 0$.

We can also consider innovations reducing the global pollution rate ξ or increasing the regeneration rate δ by various geoengineering methods. Since innovations in ξ or δ are pure public goods, there would be no research directed towards them in the laissez-faire equilibrium. This motivates our focus on technologies that might be developed by the private sector.

Finally, several different variations of the laws of motion of the environmental stock also yield similar results. For example, we could dispense with the upper bound on environmental quality, so that $\bar{S} = \infty$. In this case, the results are similar, except that a disaster can be

avoided even if dirty input production grows at a positive rate, provided that this rate is lower than the regeneration rate of the environment, δ . An alternative is to suppose that $S_{t+1} = -\xi Y_{dt} + S_t + \Delta$, so that the regeneration of the environment is additive rather than proportional to current quality. With this alternative law of motion, it is straightforward to show that the results are essentially identical to the baseline formulation because a disaster can only be avoided if Y_{dt} does not grow at a positive exponential rate in the long run.

Proposition 2 implies that some type of intervention is necessary to avoid a disaster. For a preliminary investigation of the implications of such intervention, suppose that the government can subsidize scientists to work in the clean sector, for example, using a proportional profit subsidy (financed through a lump-sum tax on the representative household).⁹ Denoting this subsidy rate by q_t , the expected profit from undertaking research in the clean sector becomes

$$\Pi_{ct} = (1 + q_t) \eta_c (1 + \gamma) (1 - \alpha) \alpha p_{ct}^{\frac{1}{1-\alpha}} L_{ct} A_{ct-1},$$

while Π_{dt} is still given by (16). This immediately implies that a sufficiently high subsidy to clean research can redirect innovation towards the clean sector.¹⁰ Moreover, while this subsidy is implemented, the ratio A_{ct}/A_{dt} grows at the rate $\gamma\eta_c$. When the two inputs are substitutes ($\varepsilon > 1$), a temporary subsidy (maintained for D periods) is sufficient to redirect all research to the clean sector. More specifically, while the subsidy is being implemented, the ratio A_{ct}/A_{dt} will increase, and when it has become sufficiently high, it will be profitable for scientists to direct their research to the clean sector even without the subsidy.¹¹ Equation (19) then implies that Y_{dt} will grow asymptotically at the same rate as $A_{ct}^{\alpha+\varphi}$.

We say that the two inputs are *strong substitutes* if $\varepsilon \geq 1/(1 - \alpha)$, or equivalently if $\alpha + \varphi \leq 0$. It follows from (19) that with strong substitutes, Y_{dt} will not grow in the long-run. Therefore, provided that the initial environmental quality is sufficiently high, a temporary subsidy is sufficient to avoid an environmental disaster. This case thus delivers the most optimistic implications of our analysis, where a temporary intervention is sufficient to redirect technical change and avoid an environmental disaster without preventing long-run growth or

⁹The results are identical with direct subsidies to the cost of clean research or with taxes on profits in the dirty sector.

¹⁰In particular, following the analysis in Appendix A, to implement a unique equilibrium where all scientists direct their research to the clean sector, the subsidy rate q_t must satisfy

$$q_t > (1 + \gamma\eta_d)^{-\varphi-1} \frac{\eta_d}{\eta_c} \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^\varphi - 1 \text{ if } \varepsilon \geq \frac{2-\alpha}{1-\alpha} \text{ and } q_t \geq (1 + \gamma\eta_c)^{(\varphi+1)} \frac{\eta_d}{\eta_c} \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^\varphi - 1 \text{ if } \varepsilon < \frac{2-\alpha}{1-\alpha}.$$

¹¹The temporary tax needs to be imposed for D periods where D is the smallest integer such that:

$$\frac{A_{ct+D-1}}{A_{dt+D-1}} > (1 + \gamma\eta_d)^{\frac{\varphi+1}{\varphi}} \left(\frac{\eta_c}{\eta_d} \right)^{\frac{1}{\varphi}} \text{ if } \varepsilon \geq \frac{2-\alpha}{1-\alpha} \text{ and } \frac{A_{ct+D-1}}{A_{dt+D-1}} \geq (1 + \gamma\eta_c)^{-\frac{\varphi+1}{\varphi}} \left(\frac{\eta_c}{\eta_d} \right)^{\frac{1}{\varphi}} \text{ if } 1 < \varepsilon < \frac{2-\alpha}{1-\alpha}$$

even creating long-run distortions. This contrasts with the Nordhaus, the Stern/Al Gore, and the Greenpeace answers discussed in the Introduction.

If, instead, the two inputs are *weak substitutes*, that is $\varepsilon \in (1, 1/(1 - \alpha))$ (or $\alpha + \varphi > 0$), then temporary intervention will not be sufficient to prevent an environmental disaster. Such an intervention can redirect all research to the clean sector, but equation (19) implies that even after this happens, Y_{dt} will grow at rate $(1 + \gamma\eta_c)^{\alpha+\varphi} - 1 > 0$. Intuitively, since $\varepsilon > 1$, as the average quality of clean machines increases, workers get reallocated towards the clean sector (because of *the market size effect*). At the same time the increase of the relative price of the dirty input over time encourages production of the dirty input (*the price effect*). As shown in the previous paragraph, in the strong substitutes case the first effect dominates. In contrast, in the weak substitutes case, where $\varepsilon < 1/(1 - \alpha)$, the second effect dominates,¹² and Y_{dt} increases even though A_{dt} is constant. In this case, we obtain the less optimistic conclusion that a temporary subsidy redirecting research to the clean sector will not be sufficient to avoid an environmental disaster; instead, similar to the Stern/Al Gore position, permanent government regulation is necessary to avoid environmental disaster. This discussion establishes the following proposition (proof in the text):

Proposition 3 *When the two inputs are strong substitutes ($\varepsilon \geq 1/(1 - \alpha)$) and \bar{S} is sufficiently high, a temporary subsidy to clean research will prevent an environmental disaster. In contrast, when the two inputs are weak substitute ($1 < \varepsilon < 1/(1 - \alpha)$), a temporary subsidy to clean research cannot prevent an environmental disaster.*

This proposition shows the importance of directed technical change: temporary incentives are sufficient to *redirect* technical change towards clean technologies, and once clean technologies are sufficiently advanced, profit-maximizing innovation and production will automatically shift towards those technologies so that environmental disaster can be avoided without further intervention.

It is also useful to note that all of the main results in this section are a consequence of endogenous and directed technical change. Our framework would correspond to a model without directed technical change if we instead assumed that scientists are randomly allocated between the two sectors. Suppose, for simplicity, that this allocation is such that the qualities of clean and dirty machines grow at the same rate (i.e., at the rate $\gamma\tilde{\eta}$ where $\tilde{\eta} \equiv \eta_c\eta_d/(\eta_c + \eta_d)$). In this case, dirty input production will grow at the rate $\gamma\tilde{\eta}$ instead of the higher rate $\gamma\eta_d$ with directed technical change. This implies that when the two inputs are strong substitutes ($\varepsilon \geq 1/(1 - \alpha)$), under *laissez-faire* a disaster will occur sooner with directed technical change

¹²A different intuition for the $\varepsilon \in (1, 1/(1 - \alpha))$ case is that improvements in the technology of the clean sector also correspond to improvements in the technology of the final good, which uses them as inputs; the final good, in turn, is an input for the dirty sector because machines employed in this sector are produced using the final good; hence, technical change in the clean sector creates a force towards the expansion of the dirty sector.

than without. But while, as we have just seen, with directed technical change a temporary subsidy can redirect innovation towards the clean sector, without directed technical change such redirecting is not possible and thus temporary interventions cannot prevent an environmental disaster.

3.3 Costs of delay

Policy intervention is costly in our framework, partly because during the period of adjustment, as productivity in the clean sector catches up with that in the dirty sector, final output increases more slowly than the case where innovation continues to be directed towards the dirty sector. Before studying the welfare costs of intervention in detail in Section 4, it is instructive to look at a simple measure of the (short-run) cost of intervention, defined as the number of periods T necessary for the economy under the policy intervention to reach the same level of output as it would have done within one period in the absence of the intervention: in other words, this is the length of the transition period or the number of periods of “slow growth” in output growth. This measure T_t (starting at time t) can be expressed as:

$$T_t = \left\lceil \frac{\ln \left(((1 + \gamma\eta_d)^{-\varphi} - 1) \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^\varphi + 1 \right)}{-\varphi \ln(1 + \gamma\eta_c)} \right\rceil \quad (21)$$

It can be verified that starting at any $t \geq 1$, we have $T_t \geq 2$ (in the equilibrium in Proposition 3 and with $\varepsilon \geq 1/(1 - \alpha)$). Thus, once innovation is directed towards the clean sector, it will take more than one period for the economy to achieve the same output growth as it would have achieved in just one period in the laissez-faire equilibrium of Proposition 1 (with innovation still directed at the dirty sector). Then, recalling that $\varphi \equiv (1 - \alpha)(1 - \varepsilon)$, the next corollary follows from equation (21) (proof omitted):

Corollary 1 *For $A_{dt-1}/A_{ct-1} \geq 1$, the short-run cost of intervention, T_t , is nondecreasing in the technology gap A_{dt-1}/A_{ct-1} and the elasticity of substitution ε . Moreover, T_t increases more with A_{dt-1}/A_{ct-1} when ε is greater.*

The (short-run) cost of intervention, T_t , is increasing in A_{dt-1}/A_{ct-1} because a larger gap between the initial quality of dirty and clean machines leads to a longer transition phase, and thus to a longer period of slow growth. In addition, T_t is also increasing in the elasticity of substitution ε . Intuitively, if the two inputs are close substitutes, final output production relies mostly on the more productive input, and therefore, productivity improvements in the clean sector (taking place during the transition phase) will have less impact on overall productivity until the clean technologies surpass the dirty ones.

The corollary shows that delaying intervention is costly, not only because of the continued environmental degradation that will result, but also because during the period of delay A_{dt}/A_{ct}

will increase further, and thus when the intervention is eventually implemented, the temporary subsidy to clean research will need to be imposed for longer and therefore there will be a longer period of slow growth (higher T). This result is clearly related to the “building on the shoulders of giants” feature of the innovation process. Furthermore, the result that the effects of ε and A_{dt-1}/A_{ct-1} on T are complementary implies that delaying the starting date of the intervention is more costly when the two inputs are more substitutable. These results imply that even though for the strong substitutes case the implications of our model are more optimistic than those of Nordhaus, it is also the case that, in contrast to the implications of his analysis, gradual and delayed intervention would have significant costs.

Overall, the analysis in this subsection has established that a simple policy intervention that “redirects” technical change towards environment-friendly technologies can help prevent an environmental disaster. Our analysis also highlights that delaying intervention may be quite costly, not only because it further damages the environment (an effect already recognized in the climate science literature), but also because it widens the gap between dirty and clean technologies, thereby inducing a longer period of catch-up with slower growth.

3.4 Complementary inputs: $\varepsilon < 1$

Although the case with $\varepsilon > 1$, in fact with $\varepsilon \geq 1/(1 - \alpha)$, is empirically more relevant, it is useful to briefly contrast these with the case where the two inputs are complements, i.e., $\varepsilon < 1$. Lemma 1 already established that when $\varepsilon < 1$, innovation will favor the less advanced sector because $\varphi > 0$: in this case, the direct productivity effect is weaker than the combination of the price and market size effects (which now reinforce each other). Thus, under *laissez-faire*, starting from a situation where dirty technologies are initially more advanced than clean technologies, innovations will first occur in the clean sector until that sector catches up with the dirty sector; from then on innovation occurs in both sectors. Therefore, in the long-run, the share of scientists devoted to the clean sector is equal to $s_c = \eta_d/(\eta_c + \eta_d)$, so that both A_{ct} and A_{dt} grow at the rate $\gamma\tilde{\eta}$, and Proposition 2 continues to apply (see Appendix A).

It is also straightforward to see that a temporary research subsidy to clean innovation cannot avert an environmental disaster because it now has no impact on the long-run allocation of scientists between the two sectors, and thus A_{ct} and A_{dt} still grow at the rate $\gamma\tilde{\eta}$. In fact, $\varepsilon < 1$ implies that long-run growth is only possible if Y_{dt} also grows without bound, which will in turn necessarily lead to an environmental disaster. Consequently, when the two inputs are complements ($\varepsilon < 1$), our model delivers the pessimistic conclusion, similar to the Greenpeace view, that environmental disaster can only be avoided if long-run growth is halted.

3.5 Direct impact of environmental on productivity

Previous studies have often used a formulation in which environmental degradation affects productivity rather than utility. But whether it affects productivity, utility or both has little impact on our main results. Specifically, let us suppose that utility is independent of S_t , and instead clean and dirty inputs ($j \in \{c, d\}$) are produced according to:

$$Y_{jt} = \Omega(S_t) L_{jt}^{1-\alpha} \int_0^1 A_{jit}^{1-\alpha} x_{jit}^\alpha di, \quad (22)$$

where Ω is an increasing function of the environmental stock S_t , with $\Omega(0) = 0$. This formulation highlights that a reduction in environmental quality negatively affects the productivity of labor in both sectors. It is then straightforward to establish that in the laissez-faire equilibrium, either the productivity reduction induced by the environmental degradation resulting from the increase in A_{dt} occurs at a sufficiently high rate that aggregate output and consumption converge to zero, or this productivity reduction is not sufficiently rapid to offset the growth in A_{dt} and an environmental disaster occurs in finite time. This result is stated in the next proposition (and proved in Appendix B).

Proposition 4 *In the laissez-faire equilibrium, the economy either reaches a disaster in finite time or consumption converges to zero over time.*

With a similar logic to our baseline model, the implementation of a temporary subsidy to clean research in this case will avoid an environmental disaster and prevent consumption from converging to zero. It can also be shown that the short-run cost of intervention is now smaller than in our baseline model, since the increase in environmental quality resulting from the intervention also allows greater consumption.

4 Optimal Environmental Policy without Exhaustible Resources

We have so far studied the behavior of the laissez-faire equilibrium and discussed how environmental disaster may be avoided. In this section, we characterize the optimal allocation of resources in this economy and discuss how it can be decentralized using “carbon” taxes and research subsidies (we continue to focus on the case where dirty input production does not use the exhaustible resource, i.e., $\alpha_2 = 0$). The socially optimal allocation will “correct” for two externalities: (1) the environmental externality exerted by dirty input producers, and (2) the knowledge externalities from R&D (the fact that in the laissez-faire equilibrium scientists do not internalize the effects of their research on productivity in the future). In addition, it will also correct for the standard static monopoly distortion in the price of machines, encouraging more intensive use of existing machines (see, for example, Aghion and Howitt, 1998, or Acemoglu, 2009). Throughout this section, we characterize a socially optimal allocation that

can be achieved with lump-sum taxes and transfers (used for raising or redistributing revenues as required). A key conclusion of the analysis in this section is that optimal policy must use both a “carbon” tax (i.e., a tax on dirty input production) and a subsidy to clean research, the former to control carbon emissions and the latter to influence the path of future research. Relying only on carbon taxes would be excessively distortionary.

4.1 The socially optimal allocation

The socially optimal allocation is a dynamic path of final good production Y_t , consumption C_t , input productions Y_{jt} , machine productions x_{jit} , labor allocations L_{jt} , scientist allocations s_{jt} , environmental quality S_t , and qualities of machines A_{jit} that maximizes the intertemporal utility of the representative consumer, (1), subject to (4), (5), (7), (8), (9), (11), and (12), with $R_t \equiv 0$ and $\alpha_2 = 0$. The following proposition is one of our main results.

Proposition 5 *The socially optimal allocation can be implemented using a tax on dirty input (a “carbon” tax), a subsidy to clean innovation, and a subsidy for the use of all machines (all proceeds from taxes/subsidies being redistributed/financed lump-sum).*

Proof. See Appendix A. ■

This result is intuitive in view of the fact that the socially optimal allocation must correct for three market failures in the economy. First, the underutilization of machines due to monopoly pricing in the laissez-faire equilibrium is corrected by a subsidy for machines. Second, the environmental externality is corrected by introducing a wedge between the marginal product of dirty input in the production of the final good and its shadow value—which corresponds to a tax τ_t on the use of dirty input. In Appendix A (proof of Proposition 5), we show that:

$$\tau_t = \frac{\xi}{\widehat{p}_{dt}} \frac{\frac{1}{1+\rho} \sum_{v=t+1}^{\infty} \left(\frac{1+\delta}{1+\rho}\right)^{v-(t+1)} I_{S_{t+1}, \dots, S_v < \bar{S}} \partial u(C_v, S_v) / \partial S}{\partial u(C_t, S_t) / \partial C}. \quad (23)$$

where \widehat{p}_{jt} denotes the shadow (producer) price of input j at time t in terms of the final good (or more formally, as shown in Appendix A, it is the ratio of the Lagrange multipliers for constraints (5) and (4)), and $I_{S_{t+1}, \dots, S_v < \bar{S}}$ takes value 1 if $S_{t+1}, \dots, S_v < \bar{S}$ and 0 otherwise. This tax reflects that at the optimum, the marginal cost of reducing the production of dirty input by one unit must be equal to the resulting marginal benefit in terms of higher environmental quality in all subsequent periods. Finally, the socially optimal allocation also internalizes the knowledge externality in the innovation possibilities frontier and allocates scientists to the sector with the higher social gain from innovation. We show in Appendix A that in the social optimum, scientists are allocated to the clean sector whenever the ratio

$$\frac{\eta_c (1 + \gamma \eta_c s_{ct})^{-1} \sum_{\tau \geq t} \frac{\partial u(C_\tau, S_\tau) / \partial C}{(1+\rho)^\tau} \widehat{p}_{c\tau}^{\frac{1}{1-\alpha}} L_{c\tau} A_{c\tau}}{\eta_d (1 + \gamma \eta_d s_{dt})^{-1} \sum_{\tau \geq t} \frac{\partial u(C_\tau, S_\tau) / \partial C}{(1+\rho)^\tau} \widehat{p}_{d\tau}^{\frac{1}{1-\alpha}} L_{d\tau} A_{d\tau}} \quad (24)$$

is greater than 1. This contrasts with the decentralized outcome where scientists are allocated according to the private value of innovation, that is, according to the ratio of the first term in the numerator over the first term in the denominator.¹³

That we need both a “carbon” tax and a subsidy to clean research to implement the social optimum (in addition to the subsidy to remove the monopoly distortions) is intuitive: the subsidy deals with future environmental externalities by directing innovation towards the clean sector, whereas the carbon tax deals more directly with the current environmental externality by reducing production of the dirty input. By reducing production in the dirty sector, the carbon tax also discourages innovation in that sector. However, using only the carbon tax to deal with both current environmental externalities and future (knowledge-based) externalities will typically necessitate a higher carbon tax, distorting current production and reducing current consumption excessively. An important implication of this result is that, without additional restrictions on policy, it is not optimal to rely only on a carbon tax to deal with global warming; one should also use additional instruments (R&D subsidies or a profit tax on the dirty sector) that direct innovation towards clean technologies, so that in the future production can be increased using more productive clean technologies.

Remark 2 To elaborate on this issue, let us refer to optimal policy using both a carbon tax and a clean research subsidy as “first-best” policy, and to optimal policy constrained to use only the carbon tax as “second-best” policy (in both cases subsidies to the machines are present). Such a second-best policy might result, for example, because R&D subsidies are ineffective or their use cannot be properly monitored. Suppose first that both first-best and second-best policies result in all scientists being always allocated to the clean sector and that the first-best policy involves a positive clean research subsidy. In this case, we can show that the carbon tax in the second-best policy must be higher than in the first-best policy. This simply follows from the fact that under the second-best policy there is no direct subsidy to clean research, and thus the carbon tax needs to be raised to indirectly “subsidize” clean research. Nevertheless, when the clean research subsidy is no longer necessary in the first-best or in cases where under either the first-best or the second-best policies there is delay in the switch to clean research, carbon taxes may end up being lower for some periods under the second-best policy than under the first-best policy (for example, because the switch to clean research may start later or finish earlier under the second-best).

¹³The knowledge externality is stark in our model because of the assumption that patents last for only one period. Nevertheless, our qualitative results do not depend on this assumption, since, even with perfectly-enforced infinite-duration patents, clean innovations create a knowledge externality for future clean innovations because of the “building on the shoulders of giants” feature of the innovation possibilities frontier.

4.2 The structure of optimal environmental regulation

In subsection 3.2, we showed that a switch to innovation in clean technologies induced by a temporary profit tax could prevent a disaster when the two inputs are substitutes. Here we show that, when the two inputs are sufficiently substitutable and the discount rate is sufficiently low, the optimal policy in Proposition 5 also involves a switch to clean innovation and only temporary interventions (except for the subsidy correcting for monopoly distortions).

Proposition 6 *Suppose that $\varepsilon > 1$ and the discount rate ρ is sufficiently small. Then all innovation switches to the clean sector in finite time, the economy grows asymptotically at the rate $\gamma\eta_c$ and the optimal subsidy on profits in the clean sector, q_t , is temporary. Moreover, if $\varepsilon > 1/(1 - \alpha)$ (but not if $1 < \varepsilon < 1/(1 - \alpha)$), then the optimal carbon tax, τ_t , is temporary.*

Proof. See Appendix B. ■

To obtain an intuition for this proposition, first note that an optimal policy requires avoiding a disaster, since a disaster leads to $\lim_{S \downarrow 0} u(C, S) = -\infty$. This in turn implies that the production of dirty input must always remain below a fixed upper bound. When the discount rate is sufficiently low, it is optimal to have positive long-run growth, which can be achieved by technical change in the production of the clean input, without growth over the production of the dirty input (because $\varepsilon > 1$). Failing to allocate all research to clean innovation in finite time would then slow down the increase in clean input production and reduce intertemporal welfare. An appropriately-chosen subsidy to clean research then ensures that innovation occurs only in the clean sector, and when A_{ct} exceeds A_{dt} by a sufficient amount, innovation in the clean sector will have become sufficiently profitable that it will continue even after the subsidy is removed (and hence there is no longer a need for the subsidy). The economy will then generate a long-run growth rate equal to the growth rate of A_{ct} , namely $\gamma\eta_c$. When $\varepsilon > 1/(1 - \alpha)$, the production of dirty input also decreases to 0 over time, and as a result, the environmental stock S_t reaches \bar{S} in finite time due to positive regeneration. This in turn ensures that the optimal carbon tax given by (23) will reach zero in finite time.¹⁴

It is also straightforward to compare the structure of optimal policy in this model to the variant without directed technical change discussed above. Since without directed technical change the allocation of scientists is insensitive to policy, redirecting innovation towards the clean sector is not possible. Consequently, optimal environmental regulation must prevent an environmental disaster by imposing an ever-increasing sequence of carbon taxes. This comparison highlights that the optimistic conclusion that optimal environmental regulation can be achieved using temporary taxes/subsidies, and with little cost in terms of long-run distortions and growth, is entirely due to the presence of directed technical change.

¹⁴This result depends on the assumption that $\partial u(C, \bar{S})/\partial S = 0$. With $\partial u(C, \bar{S})/\partial S > 0$, the optimal carbon tax may remain positive in the long run. Moreover, in practice the decline in carbon levels in the atmosphere are slower than implied by our simple equation (12), necessitating a longer-lived carbon tax.

5 Equilibrium and Optimal Policy with Exhaustible Resources

In this section we characterize the equilibrium and the optimal environmental policy when dirty input production uses the exhaustible resource (i.e., when $\alpha_2 > 0$). In particular, we will show that the presence of an exhaustible resource may help prevent an environmental disaster because it increases the cost of using the dirty input even without policy intervention. Nevertheless, the major qualitative features of optimal environmental policy are similar to the case without exhaustible resource.

In the first two subsections, we simplify the exposition by assuming that there are no privately held property rights to the exhaustible resource. In this case, the user cost of the exhaustible resource is determined by the cost of extraction and does not reflect its scarcity value. We then show that the main results generalize to the case in which the property rights to the exhaustible resource are vested in infinite-lived firms or consumers, so that the price is determined by the Hotelling rule.

5.1 The laissez-faire equilibrium

When $\alpha_2 > 0$, the structure of equilibrium remains mostly unchanged. In particular, the relative profitability of innovation in clean and dirty sectors reflects the same three effects as before: the direct productivity effect, the price effect and the market size effect identified above. The only change relative to the baseline model is that the resource stock now affects the magnitude of the price and market size effects. In particular, as the resource stock declines, the effective productivity of the dirty input also declines and its price increases, and the share of labor allocated to the dirty sector decreases with the extraction cost. The ratio of expected profits from research in the two sectors, which again determines the direction of equilibrium research, now becomes (see Appendix B):

$$\frac{\Pi_{ct}}{\Pi_{dt}} = \kappa \frac{\eta_c c(Q_t)^{\alpha_2(\varepsilon-1)}}{\eta_d} \frac{(1 + \gamma \eta_c s_{ct})^{-\varphi-1} A_{ct-1}^{-\varphi}}{(1 + \gamma \eta_d s_{dt})^{-\varphi_1-1} A_{dt-1}^{-\varphi_1}}, \quad (25)$$

where $\kappa \equiv \frac{(1-\alpha)}{(1-\alpha_1)\alpha_1^{(1+\alpha_2-\alpha_1)/(1-\alpha_1)}} \left(\frac{\alpha^{2\alpha}}{\psi^{\alpha_2} \alpha_1^{2\alpha_1} \alpha_2^{\alpha_2}} \right)^{(\varepsilon-1)}$ and $\varphi_1 \equiv (1 - \alpha_1)(1 - \varepsilon)$.

The main difference from the corresponding expression (18) in the case with $\alpha_2 = 0$ is the term $c(Q_t)^{\alpha_2(\varepsilon-1)}$ in (25). This new term, together with the assumption that $c(Q_t)$ is decreasing in Q_t , immediately implies that when the two inputs are substitutes ($\varepsilon > 1$), as the resource stock gets depleted, the incentives to direct innovations towards the clean sector will increase. Intuitively, the depletion of the resource stock increases the relative cost (price) of the dirty input, and thus reduces the market for the dirty input and encourages innovation in the clean sector (because $\varepsilon > 1$). In fact, it is straightforward to see that asymptotically there will be innovation in the clean sector only (either because the extraction cost increases sufficiently

rapidly, inducing all innovation to be directed at clean machines, or because the resource stock gets fully depleted in finite time). Then, again because $\varepsilon > 1$, the dirty input is not essential to final production and therefore, provided that initial environmental quality is sufficiently high, an environmental disaster can be avoided while the economy achieves positive long-run growth at the rate $\gamma\eta_c$. This discussion establishes the following proposition. (Appendix B provides a formal proof and also analyzes the case in which $\varepsilon < 1$).

Proposition 7 *Suppose the two inputs are substitutes ($\varepsilon > 1$). Then innovation in the long-run will be directed towards the clean sector only and the economy will grow at rate $\gamma\eta_c$. Provided that \bar{S} is sufficiently high, an environmental disaster is avoided under laissez-faire.*

The most important result in this proposition is that when an exhaustible resource is necessary for production of the dirty input, the market generates incentives for research to be directed towards the clean sector, and these market-generated incentives may be sufficient for the prevention of an environmental disaster. This contrasts with the result that an environmental disaster is unavoidable under laissez-faire without the exhaustible resource. Therefore, to the extent that in practice the increasing price of oil and the higher costs of oil extraction will create a natural move away from dirty inputs, the implications of growth are not as damaging to the environment as in the baseline case with $\alpha_2 = 0$. Nevertheless, because of the environmental and the knowledge externalities (and also because of the failure to correctly price the resource), the laissez-faire equilibrium is still Pareto suboptimal.

5.2 Optimal environmental regulation with exhaustible resources

We now briefly discuss the structure of optimal policy in the presence of an exhaustible resource. The socially optimal allocation maximizes (1) now subject to the constraints (4), (5), (6), (7), (8), (9), (11), (12), and the resource constraint $Q_t \geq 0$ for all t .

As in Section 4, the socially optimal allocation will correct for the monopoly distortion by subsidizing the use of machines and will again introduce a wedge between the shadow price of the dirty input and its marginal product in the production of the final good, equivalent to a tax on dirty input production. In addition, because the private cost of extraction is $c(Q_t)$ (i.e., does not incorporate the scarcity value of the exhaustible resource), the socially optimal allocation will also use a “resource tax” to create a wedge between the cost of extraction and the social value of the exhaustible resource. The next proposition summarizes the structure of optimal policy in this case.

Proposition 8 *The socially optimal allocation can be implemented using a “carbon” tax (i.e., a tax on the use of the dirty input), a subsidy to clean research, a subsidy on the use of all machines and a resource tax (all proceeds from taxes/subsidies being redistributed/financed lump-sum). The resource tax must be maintained forever.*

Proof. See Appendix B. ■

In the next section, we will also see that several quantitative features of the optimal policy are similar in the economies with and without exhaustible resources.

5.3 Equilibrium and optimal policy under the Hotelling rule

We next investigate the implications of having well-defined property rights to the exhaustible resource vested in price-taking infinitely-lived profit-maximizing firms (see Golosov et al., 2009, for a recent treatment of this case). This implies that the price of the exhaustible resource will be determined by the Hotelling rule.¹⁵ In particular, let us suppose for simplicity that the cost of extraction $c(Q_t)$ is constant and equal to $c > 0$. Then the price of the exhaustible resource, P_t , has to be such that the marginal value of one additional unit of extraction today must be equal to the discounted value of an additional unit extracted tomorrow. More formally, the Hotelling rule in this case takes the form

$$\frac{\partial u(C_t, S_t)}{\partial C} (P_t - c) = \frac{1}{1 + \rho} \frac{\partial u(C_{t+1}, S_{t+1})}{\partial C} (P_{t+1} - c). \quad (26)$$

We further simplify the analysis by assuming a constant coefficient of relative risk aversion σ in consumption, and separable preferences between consumption and environmental quality:

$$u(C_t, S_t) = \frac{C_t^{1-\sigma}}{1-\sigma} + \nu(S_t),$$

where $\nu' > 0$ and $\nu'' < 0$. Then the Hotelling rule, (26), implies that the price P_t of the resource must asymptotically grow at the interest rate r , given from the consumption Euler as:

$$r = (1 + \rho)(1 + g)^\sigma - 1, \quad (27)$$

where g is the asymptotic growth rate of consumption.

The next proposition shows that relative to the case analyzed in the previous two subsections, avoiding an environmental disaster becomes more difficult when the price of the exhaustible resource is given by the Hotelling rule.

Proposition 9 *If the discount rate ρ and the elasticity of substitution ε are both sufficiently high (in particular, if $\ln(1 + \rho) > [(1 - \alpha_1)/\alpha_2] \ln(1 + \gamma \max(\eta_d, \eta_c))$ and $\varepsilon > 1/(2 - \alpha_1 - \alpha)$), then innovation asymptotically occurs in the clean sector only and a disaster is avoided under laissez-faire provided that the initial environmental quality, \bar{S} , is sufficiently high. However, if the discount rate and the elasticity of substitution are sufficiently low (in particular, if $\ln(1 + \rho) < (1/\varepsilon - (1 - \alpha) - \alpha_2\sigma) \ln(1 + \gamma\eta_c)/\alpha_2$ and $\ln(1 + \rho) \neq (1 - \alpha_1) \ln(1 + \gamma\eta_d)/\alpha_2$), then a disaster cannot be avoided under laissez-faire.*

¹⁵Yet another alternative would be to have the exhaustible resource owned by a single entity (or consortium), which would not only choose its price according to its scarcity but would also attempt to deviate from the Hotelling rule to internalize the environmental externalities. We find this case empirically less relevant and do not focus on it.

Proof. See Appendix B. ■

Intuitively, if the price of the resource P_t increases more slowly over time than productivity in the dirty sector, A_{dt} , then under laissez-faire, innovation continues to take place in the dirty sector forever and the growth in the production of the dirty input leads to an environmental disaster. This case arises when the discount rate ρ is sufficiently small. An environmental disaster can only be avoided if the price P_t increases sufficiently fast so that in finite time innovation shifts entirely to the clean sector. This in turn requires that the discount rate ρ be sufficiently high. However, for the same reasons as those highlighted in Section 3, such a switch is not sufficient to avoid an environmental disaster unless clean and dirty sectors are “strong substitutes,” which now corresponds to the case where $\varepsilon > 1/(2 - \alpha_1 - \alpha)$.

It can also be shown that a temporary research subsidy is now sufficient to avoid a disaster when $\varepsilon > 1/[1 - \alpha + \alpha_2 (\ln(1 + \rho) / \ln(1 + \gamma\eta_c) + \sigma)]$. This threshold is lower than the corresponding threshold $1/(1 - \alpha)$ in the case without the exhaustible resource because dirty inputs are now using the exhaustible resource, which has a price growing at the rate $(1 + \rho)(1 + \gamma\eta_c)^\sigma - 1$. This is also the reason why this threshold is decreasing in the share of the exhaustible resource in the production of dirty input. Finally, one can show that the optimal policy is identical to that characterized in subsection 5.2, except that the resource tax is no longer necessary.

6 Quantitative Evaluation

In this section, we report the results of a first quantitative evaluation of the economic forces introduced in this paper. We start with the economy without exhaustible resources (i.e., $\alpha_2 = 0$). We then briefly discuss the economy with an exhaustible resource. Our objective is not to provide a comprehensive quantitative evaluation, but to highlight the effects of different values of the discount rate and the elasticity of substitution on the form of optimal environmental regulation and the resulting timing of a switch (of R&D and production) to clean technology. To highlight the new implications of directed technical change, we choose the parameters to make our exercise as similar to existing quantitative analyses as possible.

We take a period in our model to correspond to 5 years. We set $\eta_c = \eta_d = 0.02$ (per annum) and $\gamma = 1$ so that the long-run annual growth rate is equal to 2% (which matches Nordhaus’ assumptions in his 2007 DICE calibration). We take $\alpha = 1/3$ (so that the share of national income spent on machines is approximately equal to the share of capital). We suppose that before the implementation of the optimal policy the carbon tax is set at 0. But to focus on the implications of the environmental externality, we assume that the subsidy to machines is present throughout. We compute A_{ct-1} and A_{dt-1} to match the implied values of Y_{ct-1} and Y_{dt-1} to the production of nonfossil and fossil fuel in the world primary energy supply from 2002 to 2006 (according to the Energy Information Administration data). Note that in all our

exercises, when ε varies, A_{ct-1} and A_{dt-1} also need to be adjusted (in particular, a higher ε leads to a higher ratio of A_{ct-1}/A_{dt-1}).

Estimating the economy-wide elasticity of substitution is beyond the scope of the current paper. We simply note that since fossil and nonfossil fuels should be close substitutes (at the very least, once nonfossil fuels can be transported efficiently), reasonable values of ε should be quite high. Throughout the following calibration exercise, we consider two different values for ε : a low value of $\varepsilon = 3$ and a high value of $\varepsilon = 10$. Contrasting what happens under these two values will allow us to highlight the crucial role of the elasticity of substitution in determining the form of the optimal policy.

6.1 Parameter choices

To relate the environmental quality variable S to the atmospheric concentration of carbon, we use a common approximation to the relationship between the increase in temperature since preindustrial times (in degrees Celsius), Δ , and the atmospheric concentration of carbon dioxide (in ppm), C_{CO_2} : $\Delta \simeq 3 \log_2(C_{CO_2}/280)$. This equation implies that a doubling of atmospheric concentration in CO_2 (since preindustrial times, when the concentration was equal to 280 ppm) leads to a $3^\circ C$ increase in current temperature (see, e.g., Pachauri et al., 2007). We then express S as a decreasing function of Δ and thus of C_{CO_2} , so that $S = 0$ corresponds to a level of temperature change Δ approximating “disaster temperature,” $\Delta_{disaster}$ (described below). More specifically, we set

$$S = 280 \times 2^{\Delta_{disaster}/3} - \max\{C_{CO_2}, 280\}.$$

Furthermore, we now relax the assumption that $S_0 = \bar{S}$ and set the initial environmental quality S_0 to correspond to the current atmospheric concentration of 379 ppm (\bar{S} , in turn, corresponds to $C_{CO_2} = 280$ ppm, the preindustrial value).

We then estimate parameter ξ from the observed value of Y_d and the annual emission of CO_2 (ξY_d in our model) between 2002 and 2006 according to the Energy Information Administration. Finally, we choose δ such that only half of the amount of emitted carbon contributes to increasing CO_2 concentration in the atmosphere (the rest being offset by “environmental regeneration,” see again Pachauri et al., 2007).

Nordhaus—and much of the literature following his work—assumes that environmental quality affects aggregate productivity. We find it more reasonable that high temperature levels and high concentrations of carbon dioxide affect utility as well as production, and we formulated our model under the assumption that environmental quality directly affects utility. To highlight the similarities and the differences between our model and existing quantitative models with exogenous technology, we choose the parameters such that the welfare consequences of changes in temperature (for the range of changes observed so far) are the same in our model as in

previous work. We parameterize the utility function as

$$u(C_t, S_t) = \frac{(\phi(S_t) C_t)^{1-\sigma}}{1-\sigma}, \quad (28)$$

with $\sigma = 2$, which matches Nordhaus’s choice of intertemporal elasticity of substitution. In addition, this utility function contains the term $\phi(S)$ for the costs from the degradation of environmental quality. We choose this function as

$$\phi(S) = \varphi(\Delta(S)) \equiv \frac{(\Delta_{disaster} - \Delta(S))^\lambda - \lambda \Delta_{disaster}^{\lambda-1} (\Delta_{disaster} - \Delta(S))}{(1-\lambda) \Delta_{disaster}^\lambda}, \quad (29)$$

with $\Delta_{disaster} = 6.9^\circ\text{C}$, and matching this function with Nordhaus’s damage function over the range of temperature increases up to 3°C leads to a value of $\lambda = 0.3492$.¹⁶

6.2 Results

The debate between Stern and Nordhaus highlighted the importance of the discount rate when determining the optimal environmental policy. Here we consider two different values for the discount rate: the Stern discount rate of 0.001 per annum (which we write as $\rho = 0.001$), and the Nordhaus discount rate of 0.015 per annum ($\rho = 0.015$, which, as in Nordhaus, corresponds to an annual long-run interest rate of about $r = \rho + \sigma g = 5.5\%$).

Figure 1 shows the subsidy to the clean sector, the allocation of scientists to clean technologies, the “carbon” tax, the share of clean inputs in total production, and the increase in temperature in the optimal allocation for different values of ε and ρ .

This figure shows very similar patterns for $\rho = 0.015$ and $\rho = 0.01$ when $\varepsilon = 10$. In fact, the blue and green curves referring to these two cases are not distinguishable in the figure. Figure 1B shows that when $\varepsilon = 10$ or when $\varepsilon = 3$ and $\rho = 0.001$, the optimal policy involves an immediate switch of all research activities toward clean technologies. When $\varepsilon = 3$ and $\rho = 0.015$, the switch towards clean research occurs around year 50. As shown in Figure 1A, the optimal subsidy to clean research is temporary, and it is lower and of shorter duration when $\varepsilon = 10$, because in this case the initial gap between clean and dirty technologies consistent

¹⁶ φ is a strictly decreasing and concave function, with $\varphi(0) = 1$, $\varphi(\Delta_{disaster}) = 0$, $\varphi'(0) = 0$ and $\lim_{\Delta \rightarrow \Delta_{disaster}} \varphi'(\Delta) = -\infty$. This functional form ensures that our assumptions on the utility function, (2) and (3), are satisfied. Note that (29) defines a flexible family of continuous functions parameterized by λ . As $\lambda \rightarrow 1$, this function converges to $\varphi_1(\Delta) = (1 - \Delta/\Delta_{disaster})(1 - \ln(1 - \Delta/\Delta_{disaster}))$ for all $\Delta \in [0, \Delta_{disaster})$ (from L’Hopital’s rule) and $\varphi_1(\Delta_{disaster}) = 0$, and as $\lambda \rightarrow 1$, it converges (pointwise) to the “step function” $\varphi_0(\Delta) = 1$ for all $\Delta \in [0, \Delta_{disaster})$ and $\varphi_0(\Delta) = 0$ for $\Delta = \Delta_{disaster}$. The value $\Delta_{disaster} = 6.9^\circ\text{C}$ corresponds to 1.5 times the highest estimate of the temperature increase that would eventually lead to the melting of the Greenland Ice Sheet (Pachauri et al., 2007). In Nordhaus’s DICE model, output is affected by temperature through a multiplicative term $\Omega(\Delta) = (1 + 0.0028388\Delta^2)^{-1}$ in the aggregate production function. We compute the parameter λ so as to match our function φ with Ω over the range of temperature increases up to 3°C (more precisely, we minimize the L^2 -norm of the difference $\Omega - \varphi$ on the interval $[0, 3]$). With this choice of φ function, our model generates effects that are very close to those obtained in Nordhaus’s calibration exercises for increases in temperature less than 3°C .

Figure 1: Optimal environmental policy for different values of ε and ρ

with the observed share of dirty inputs is smaller. When $\varepsilon = 3$, the optimal subsidy is larger and lasts longer, particularly when $\rho = 0.015$, because in this case the switch to clean research occurs later.

Figure 1C shows that when $\varepsilon = 10$, there is only a very low of carbon tax for a limited period because the rapid switch to clean inputs makes this tax unnecessary.¹⁷ Again, in contrast, when $\varepsilon = 3$ and $\rho = 0.015$, because the switch of both innovation and production to the clean sector is delayed, there is a much higher and initially (for over 250 years) increasing carbon tax. Figure 1D shows that when $\varepsilon = 10$, the clean sector takes over most of input production quite rapidly (it takes 30 years only for 90% of input production to switch to the clean sector). In contrast, when $\varepsilon = 3$ and $\rho = 0.001$, even though the switch to clean research is immediate, it takes much longer (for over 150 years) for 90% of inputs to be supplied by

¹⁷This result should be interpreted with caution. For example, if we introduce restrictions on research subsidies or allow them to be less than fully effective, then there would be a greater role for the carbon tax.

the clean sector. Figure 1E shows that when $\varepsilon = 10$, there is a small increase, followed by a decrease, in temperature (going back to its preindustrial level after about 90 years). The pattern is similar, though the increase and the subsequent decline are more protracted when $\varepsilon = 3$ and $\rho = 0.001$. Finally, when $\varepsilon = 3$ and $\rho = 0.015$, temperature keeps increasing for about 250 years before reaching a maximum fairly close to the disaster level.

Overall, the above exercise suggests that if the elasticity of substitution between clean and dirty inputs is sufficiently high, then whether one uses the Nordhaus or the Stern discount rate has little bearing on the nature of the optimal environmental policy.

Corollary 1 in subsection 3.3 related the costs of delayed intervention to the number of additional periods of slow growth that such a delay would induce. Table 1 here shows the welfare costs of delaying the implementation of the optimal policy (i.e., of maintaining the clean innovation subsidy and the carbon tax at zero for a while before implementing the optimal policy).¹⁸ Welfare costs are measured as the equivalent percentage reduction in per period consumption relative to the allocation with immediate intervention (we assume that when intervention starts, it takes the optimal form). The numbers in the table correspond to different values of the elasticity of substitution ε (with the initial value A_{ct-1} and A_{dt-1} being adjusted accordingly), the discount rate ρ and the amount of delay. The table shows that delay costs can be substantial. For example, with $\varepsilon = 10$ and $\rho = 0.001$, a 10 year delay is equivalent to a 14.02% decline in consumption (when $\rho = 0.015$, the corresponding number is 1.92%). Moreover, the cost of delay increases with the duration of the delay and the elasticity of substitution between the two inputs. Intuitively, when the two inputs are close substitutes, further advances in the dirty technology that occur before the optimal policy is implemented do not contribute much to aggregate output once the switch to clean research and production takes place. The cost of delay also decreases with the discount rate because the benefit from delaying intervention, due to higher consumption early on, increases with the discount rate. It is also noteworthy that the variations in the delay cost resulting from changes in ε and ρ are of the same order of magnitude. This suggests that the elasticity of substitution between clean and dirty input is as important a consideration as the discount rate when assessing the costs of delaying intervention.

Table 1: Welfare costs of delayed intervention as a function of the elasticity of substitution and the discount rate

(Percentage reductions in consumption relative to immediate intervention)

Elasticity of substitution ε	10		3	
Discount rate ρ	0.001	0.015	0.001	0.015
delay = 10 years	8.75	1.87	2.71	0.05
delay = 20 years	14.02	1.92	4.79	0.12
delay = 30 years	17.65	1.99	6.88	0.23

¹⁸The optimal subsidy on machines is maintained during the period of delay.

Finally, we briefly discuss the welfare costs of relying solely on a carbon (input) tax instead of combining it with the subsidy to clean research (i.e., the “second-best” instead of “first-best” derived in Proposition 6). Without the subsidy to clean research, the carbon tax needs to be significantly higher. For example, when $\varepsilon = 10$ and $\rho = 0.015$, the initial value of the carbon tax in the second-best needs to be 20 times higher than in the first-best. The higher tax level creates a greater reduction in production and consumption in the short run. Table 2 shows that the welfare loss in the second-best relative to the first-best can be significant (though it is typically smaller than the costs of delay shown in Table 1). It is smaller when the elasticity of substitution is high, since in this case a relatively small carbon tax is sufficient to redirect R&D towards clean technologies; and it is greater when the discount rate is high, because a higher discount rate puts a higher weight on earlier periods where a significantly higher carbon tax needs to be imposed in the second-best.

Table 2: Welfare costs of relying solely on carbon tax as a function of the elasticity of substitution and the discount rate

(Percentage reductions in consumption relative to the optimal policy)

Elasticity of substitution ε	10		3	
Discount rate ρ	0.001	0.015	0.001	0.015
Welfare cost	0.95	1.58	1.74	2.70

6.3 Optimal policies with exhaustible resources

In Appendix B, we report the quantitative results for the version of the model with an exhaustible resource. Figure 2 in Appendix B shows that the implied path of optimal policy is remarkably similar to the case without an exhaustible resource. We again find that when $\varepsilon = 10$ or when $\varepsilon = 3$ and $\rho = 0.001$, the switch to clean innovation is immediate. When $\varepsilon = 3$ and $\rho = 0.015$, the switch to clean innovation is again delayed and takes slightly more than 50 years. The behavior of temperature and taxes in all cases is very similar to Figure 1 (but we can see that when the switch to clean innovation is immediate, production switches faster towards the clean sector because of the cost of the exhaustible resource). Intuitively, the similarity is due to the fact that optimal policy does not run up against the exhaustibility constraint.

7 Conclusion

In this paper we introduced endogenous and directed technical change in a growth model with environmental constraints and limited resources. We characterized the structure of equilibria and the dynamic tax/subsidy policies that achieve sustainable growth or maximize intertemporal welfare. The long-run properties of both the laissez-faire equilibrium and the social

optimum (or the necessary policies to avoid environmental disaster) are related to the degree of substitutability between clean and dirty inputs, to whether dirty input production uses exhaustible resources, and to initial environmental and resource stocks.

The main implications of factoring in the importance of directed technical change are as follows: (i) when the inputs are sufficiently substitutable, sustainable long-run growth can be achieved using temporary policy intervention (e.g., a temporary research subsidy to the clean sector), and need not involve long-run distortions; (ii) optimal policy involves both “carbon taxes” and research subsidies, so that excessive use of carbon taxes can be avoided; (iii) delay in intervention is costly: the sooner and the stronger the policy response, the shorter will the slow growth transition phase be; (iv) the use of an exhaustible resource in dirty input production helps the switch to clean innovation under *laissez-faire*. Thus the response of technology to policy leads to a more optimistic scenario than what emerges from models with exogenous technology. However, directed technical change also calls for immediate and decisive action in contrast to the implications of several exogenous technology models used in previous economic analyses.

A simple quantitative evaluation suggests that, provided that the elasticity of substitution between clean and dirty inputs is sufficiently high, optimal environmental regulation should involve an immediate switch of R&D resources to clean technology, followed by a gradual switch of all production to clean inputs. This conclusion appears robust to the range of discount rates used in the Stern report and in Nordhaus’s work (which lead to very different policy conclusions in models with exogenous technology). Interestingly, in most cases, optimal environmental regulation involves small carbon taxes because research subsidies are able to redirect innovation to clean technologies before there is more extensive environmental damage.

Our paper is a first step towards a comprehensive framework that can be used for theoretical and quantitative analysis of environmental regulation with endogenous technology. Several directions of future research appear fruitful. First, it would be useful to develop a multi-country model with endogenous technology and environmental constraints, which can be used to discuss issues of global policy coordination and the degree to which international trade should be linked to environmental policies. Second, an interesting direction is to incorporate “environmental risk” into this framework, for example, because of the *ex ante* uncertainty on the regeneration rate, δ , or on future costs of environmental damage. Another line of important future research would be to exploit macroeconomic and microeconomic (firm- and industry-level) data to estimate the relevant elasticity of substitution between clean and dirty inputs.

Appendix A

Solving for the laissez-faire equilibrium

In this Appendix we solve for the profit-maximization of machine producers, and express the price and labor allocation ratio as a function of the relative aggregate productivities of clean and dirty technologies in the laissez-faire equilibrium.

The profit-maximization problem of the producer of machine i at time t in sector $j \in \{c, d\}$ can be written as

$$\max_{x_{jit}, L_{jt}} \left\{ p_{jt} L_{jt}^{1-\alpha} \int_0^1 A_{jit}^{1-\alpha} x_{jit}^\alpha di - w_t L_{jt} - \int_0^1 p_{jit} x_{jit} di \right\},$$

and leads to the following iso-elastic inverse demand curve:

$$x_{jit} = \left(\frac{\alpha p_{jt}}{p_{jit}} \right)^{\frac{1}{1-\alpha}} A_{jit} L_{jt}. \quad (\text{A.30})$$

The monopolist producer of machine i in sector j chooses p_{jit} and x_{jit} to maximize profits $\pi_{jit} = (p_{jit} - \psi) x_{jit}$, subject to the inverse demand curve (A.30). Given this iso-elastic demand, the profit-maximizing price is a constant markup over marginal cost, thus $p_{jit} = \psi/\alpha$. Recalling the normalization $\psi \equiv \alpha^2$, this implies that $p_{jit} = \alpha$ and thus the equilibrium demand for machines i in sector j is obtained as

$$x_{jit} = p_{jt}^{\frac{1}{1-\alpha}} L_{jt} A_{jit}. \quad (\text{A.31})$$

Equilibrium profits for the monopolist are then given by (15) in the text.

Next combining equation (A.31) with the first-order condition with respect to labor, $(1 - \alpha) p_{jt} L_{jt}^{-\alpha} \int_0^1 A_{jit}^{1-\alpha} x_{jit}^\alpha di = w_t$ and using (10) gives the relative prices of clean and dirty inputs as

$$\frac{p_{ct}}{p_{dt}} = \left(\frac{A_{ct}}{A_{dt}} \right)^{-(1-\alpha)}. \quad (\text{A.32})$$

This equation formalizes the natural idea that the input produced with more productive machines will be relatively cheaper.

Equation (A.31) together with (5) gives the equilibrium production level of input j as

$$Y_{jt} = (p_{jt})^{\frac{\alpha}{1-\alpha}} A_{jt} L_{jt}. \quad (\text{A.33})$$

Combining (A.33) with (13), then using (A.32) and the definition of $\varphi \equiv (1 - \alpha)(1 - \varepsilon)$, we obtain the relationship between relative productivities and relative employment as:

$$\frac{L_{ct}}{L_{dt}} = \left(\frac{p_{ct}}{p_{dt}} \right)^{-\frac{\varphi-1}{1-\alpha}} \frac{A_{dt}}{A_{ct}} = \left(\frac{A_{ct}}{A_{dt}} \right)^{-\varphi}. \quad (\text{A.34})$$

Finally, combining (A.32) and (A.34) with (17) gives (18) in the text.

Equilibrium allocations of scientists

We now characterize the equilibrium allocation(s) of innovation effort across the two sectors for any value of the elasticity parameter ε , and provide a proof of Lemma 1. Defining

$$f(s) \equiv \frac{\eta_c}{\eta_d} \left(\frac{1 + \gamma\eta_c s}{1 + \gamma\eta_d(1-s)} \right)^{-\varphi-1} \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^{-\varphi},$$

for $s \in [0, 1]$, we can rewrite (18) as $\Pi_{ct}/\Pi_{dt} = f(s_{ct})$. Clearly, if $f(1) > 1$, then $s = 1$ is an equilibrium; if $f(0) < 1$, then $s = 0$ is an equilibrium; and finally if $f(s^*) = 1$ for some $s^* \in (0, 1)$, then s^* is an equilibrium. Given these observations, we have:

1. If $1 + \varphi > 0$ (or equivalently $\varepsilon < (2 - \alpha)/(1 - \alpha)$), then $f(s)$ is strictly decreasing in s . Then it immediately follows that: (i) if $f(1) > 1$, then $s = 1$ is the unique equilibrium (we only have a corner solution in that case); (ii) if $f(0) < 1$, then $s = 0$ is the unique equilibrium (again a corner solution); (iii) if $f(0) > 1 > f(1)$, then by continuity there exists a unique $s^* \in (0, 1)$ such that $f(s^*) = 1$, which is the unique (interior) equilibrium.

2. If $1 + \varphi < 0$ (or equivalently $\varepsilon > (2 - \alpha)/(1 - \alpha)$), then $f(s)$ is strictly increasing in s . In that case: (i) if $1 < f(0) < f(1)$, then $s = 1$ is the unique equilibrium; (ii) if $f(0) < f(1) < 1$, then $s = 0$ is the unique equilibrium; (iii) if $f(0) < 1 < f(1)$, then there are three equilibria, an interior one $s = s^* \in (0, 1)$ where s^* is such that $f(s^*) = 1$, $s = 0$ and $s = 1$.

3. If $1 + \varphi = 0$, then $f(s) \equiv f$ is a constant. If f is greater than 1, then $s = 1$ is the unique equilibrium; if it is less than one, then $s = 0$ is the unique equilibrium.

This characterizes the allocation of scientists and implies the results in Lemma 1. ■

Proof of Proposition 1

Assumption 1 together with the characterization of equilibrium allocation of scientists above implies that initially innovation will occur in the dirty sector only ($s_{dt} = 1$ and $s_{ct} = 0$). From (11), this widens the gap between clean and dirty technologies and ensures that $s_{dt+1} = 1$ and $s_{ct+1} = 0$, and so on in subsequent periods. This shows that under Assumption 1, the equilibrium is uniquely defined under laissez-faire and involves $s_{dt} = 1$ and $s_{ct} = 0$ for all t . ■

Proof of Proposition 5

Let λ_t denote the Lagrange multiplier for (4), which is naturally also the shadow value of one unit of final good production. The first-order condition with respect to Y_t imply that this shadow value is also equal to the Lagrange multiplier for (8), so that it is also equal to the shadow value of one unit of consumption. Then the first-order condition with respect to C_t yields

$$\lambda_t = \frac{1}{(1 + \rho)^t} \frac{\partial u(C_t, S_t)}{\partial C}, \tag{A.35}$$

so that the shadow value of the final good is equal to the marginal utility of consumption.

Next, letting ω_t denote the Lagrange multiplier for the environmental equation (12), the first-order condition with respect to S_t gives

$$\omega_t = \frac{1}{(1+\rho)^t} \frac{\partial u(C_t, S_t)}{\partial S} + (1+\delta) I_{S_t < \bar{S}} \omega_{t+1}, \quad (\text{A.36})$$

where $I_{S_t < \bar{S}}$ is equal to 1 if $S_t < \bar{S}$ and to 0 otherwise. This implies that the shadow value of environmental quality at time t is equal to the marginal utility that it generates in this period plus the shadow value of $(1+\delta)$ units of environmental quality at time $t+1$ (as one unit of environmental quality at time t generates $1+\delta$ units at time $t+1$). Solving (A.36) recursively, we obtain that the shadow value of environmental quality at time t is:

$$\omega_t = \sum_{v=t}^{\infty} (1+\delta)^{v-t} \frac{1}{(1+\rho)^v} \frac{\partial u(C_v, S_v)}{\partial S} I_{S_t, \dots, S_v < \bar{S}}, \quad (\text{A.37})$$

where $I_{S_t, \dots, S_v < \bar{S}}$ takes value 1 if $S_t, \dots, S_v < \bar{S}$ and 0 otherwise. Given the assumption that $\partial u(C, \bar{S}) / \partial S = 0$, this equation also implies that if for all $\tau > T$, $S_\tau = \bar{S}$, then $\omega_t = 0$ for all $t > T$.

Defining λ_{jt} as the Lagrange multiplier for (5), the ratio λ_{jt}/λ_t can be interpreted as the shadow price of input j at time t (relative to the price of the final good). To emphasize this interpretation, we will denote this ratio by \hat{p}_{jt} . The first-order conditions with respect to Y_{ct} and Y_{dt} then give

$$\begin{aligned} Y_{ct}^{-\frac{1}{\varepsilon}} \left(Y_{ct}^{\frac{\varepsilon-1}{\varepsilon}} + Y_{dt}^{\frac{\varepsilon-1}{\varepsilon}} \right)^{\frac{1}{\varepsilon-1}} &= \hat{p}_{ct} \\ Y_{dt}^{-\frac{1}{\varepsilon}} \left(Y_{ct}^{\frac{\varepsilon-1}{\varepsilon}} + Y_{dt}^{\frac{\varepsilon-1}{\varepsilon}} \right)^{\frac{1}{\varepsilon-1}} - \frac{\omega_{t+1}\xi}{\lambda_t} &= \hat{p}_{dt}. \end{aligned} \quad (\text{A.38})$$

These equations imply that compared to the laissez-faire equilibrium, the social planner introduces a wedge of $\omega_{t+1}\xi/\lambda_t$ between the marginal product of the dirty input in the production and its price. This wedge $\omega_{t+1}\xi/\lambda_t$ is equal to the environmental cost of an additional unit of the dirty input (evaluated in terms of units of the final good at time t ; recall that one unit of dirty production at time t destroys ξ units of environmental quality at time $t+1$). Naturally, this wedge is also equivalent to a tax of

$$\tau_t = \frac{\omega_{t+1}\xi}{\lambda_t \hat{p}_{dt}} \quad (\text{A.39})$$

on the use of dirty input by the final good producer. This tax rate will be higher when the shadow value of environmental quality is greater, when the marginal utility of consumption today is lower, and when the price of dirty input is lower. Plugging (A.37) and (A.35) in (A.39) we get (23).

Next, the subsidy to the use of all machines can be derived from the first-order condition with respect to x_{ji} :

$$x_{jit} = \left(\frac{\alpha}{\psi} \hat{p}_{jt} \right)^{\frac{1}{1-\alpha}} A_{jit} L_{jt}. \quad (\text{A.40})$$

Comparing this expression to the equilibrium inverse demand, (A.30) highlights that existing machines will be used more intensively in the socially-planned allocation. This is a natural consequence of the monopoly distortions and can also be interpreted as the socially-planned allocation involving a subsidy of $1 - \alpha$ in the use of machines, so that their price should be identical to the marginal cost, i.e., $(1 - (1 - \alpha))\psi/\alpha = \psi \equiv \alpha^2$.

We can combine (A.40) with (5) to obtain:

$$Y_{jt} = \left(\frac{\alpha}{\psi} \widehat{p}_{jt} \right)^{\frac{\alpha}{1-\alpha}} A_{jt} L_{jt} \quad (\text{A.41})$$

so that for given price, average technology and labor allocation, the production of each input is scaled up by a factor $\alpha^{\frac{-\alpha}{1-\alpha}}$ compared to the laissez-faire equilibrium (this results from the more intensive use of machines in the socially-planned allocation).

Finally, the socially optimal allocation must correct for the knowledge externality. Let μ_{jt} denote the Lagrange multiplier for equation (11) for $j = c, d$ (corresponding to the shadow value of average productivity in sector j at time t). The relevant first-order condition gives:

$$\mu_{jt} = \lambda_t \left(\frac{\alpha}{\psi} \right)^{\frac{\alpha}{1-\alpha}} (1 - \alpha) \widehat{p}_{jt}^{\frac{1}{1-\alpha}} L_{jt} + (1 + \gamma \eta_j s_{jt+1}) \mu_{j,t+1}. \quad (\text{A.42})$$

Intuitively, the shadow value of a unit increase in average productivity in sector $j \in \{c, d\}$ is equal to its marginal contribution to time- t utility plus its shadow value at time $t + 1$ times $(1 + \gamma \eta_j s_{jt+1})$ (the number of units of productivity created out of it at time $t + 1$). This last term captures the intertemporal knowledge externality.

At the optimum, scientists will be allocated towards the sector with the higher social gain from innovation, as measured by $\gamma \eta_j \mu_{jt} A_{jt-1}$. Using (A.42), we then have that the social planner will allocate scientists to the clean sector whenever the ratio

$$\frac{\eta_c (1 + \gamma \eta_c s_{ct})^{-1} \sum_{\tau \geq t} \lambda_\tau \widehat{p}_{c\tau}^{\frac{1}{1-\alpha}} L_{c\tau} A_{c\tau}}{\eta_d (1 + \gamma \eta_d s_{dt})^{-1} \sum_{\tau \geq t} \lambda_\tau \widehat{p}_{d\tau}^{\frac{1}{1-\alpha}} L_{d\tau} A_{d\tau}} \quad (\text{A.43})$$

is greater than 1 (combining (A.35) and (A.43) we obtain (24)) The social planner can implement the optimal allocation through a subsidy q_t to clean research. To determine this subsidy, first note that in the optimal allocation the shadow values of the clean and dirty inputs satisfy

$$\widehat{p}_{ct}^{\frac{1}{1-\alpha}} A_{ct} = \widehat{p}_{dt}^{\frac{1}{1-\alpha}} A_{dt}. \quad (\text{A.44})$$

Then, using (A.38), (A.41) and (A.44), we obtain:

$$\frac{L_{ct}}{L_{dt}} = (1 + \tau_t)^\varepsilon \left(\frac{A_{ct}}{A_{dt}} \right)^{-\varphi}. \quad (\text{A.45})$$

Next using (A.40), pre-tax profits are $\pi_{jit} = (1 - \alpha) \left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}} \hat{p}_{jt}^{\frac{1}{1-\alpha}} A_{jit} L_{jt}$. Therefore, for given subsidy q_t , the ratio of expected profits from innovation in sectors c and d , the equivalent of (18) in the text, can be written as

$$\frac{\Pi_{ct}}{\Pi_{dt}} = (1 + q_t) \frac{\eta_c}{\eta_d} \left(\frac{1 + \gamma \eta_c s_{ct}}{1 + \gamma \eta_d s_{dt}} \right)^{-\varphi-1} (1 + \tau_t)^\varepsilon \left(\frac{A_{ct-1}}{A_{dt-1}} \right)^{-\varphi}. \quad (\text{A.46})$$

Clearly, when the optimal allocation involves $s_{ct} = 1$, we can choose q_t to make this expression greater than one. Or more explicitly, we can set

$$q_t \geq \hat{q}_t \equiv \frac{\eta_d}{\eta_c} (1 + \gamma \eta_d)^{-\varphi-1} (1 + \tau_t)^{-\varepsilon} \left(\frac{A_{dt-1}}{A_{ct-1}} \right)^{-\varphi} - 1.$$

When the optimal allocation involves $s_{ct} \in (0, 1)$, then setting q_t to ensure that $\Pi_{ct}/\Pi_{dt} = 1$ achieves the desired objective. ■

Appendix B: Omitted Proofs and Further Details (Not for Publication)

Allocation of scientists in laissez-faire equilibrium when the inputs are complementary ($\varepsilon < 1$)

Proposition 10 *Under Assumption 1 and if $\varepsilon < 1$, there is a unique equilibrium in laissez-faire where innovation first occurs in the clean sector, then occurs in both sectors, and asymptotically the share of scientists devoted to the clean sector is given by $s_c = \eta_d / (\eta_c + \eta_d)$; the long-run growth rate of dirty input production in this case is $\gamma\tilde{\eta}$, where $\tilde{\eta} \equiv \eta_c\eta_d / (\eta_c + \eta_d)$.*

This proposition is proved using the following lemma:

Lemma 2 *When $\varepsilon < 1$, long-run equilibrium innovation will be in both sectors, so that the equilibrium share of scientists in the clean sector converges to $s_c = \eta_d / (\eta_c + \eta_d)$.*

Proof. Suppose that at time t innovation occurred in both sectors so that $\Pi_{ct}/\Pi_{dt} = 1$. Then from (18), we have

$$\frac{\Pi_{ct+1}}{\Pi_{dt+1}} = \left(\frac{1 + \gamma\eta_c s_{ct+1}}{1 + \gamma\eta_d s_{dt+1}} \right)^{-\varphi-1} \left(\frac{1 + \gamma\eta_c s_{ct}}{1 + \gamma\eta_d s_{dt}} \right).$$

Innovation will therefore occur in both sectors at time $t+1$ whenever the equilibrium allocation of scientists (s_{ct+1}, s_{dt+1}) at time $t+1$ is such that

$$\frac{1 + \gamma\eta_c s_{ct+1}}{1 + \gamma\eta_d s_{dt+1}} = \left(\frac{1 + \gamma\eta_c s_{ct}}{1 + \gamma\eta_d s_{dt}} \right)^{\frac{1}{\varphi+1}}. \quad (\text{B.1})$$

This equation defines $s_{ct+1}(= 1 - s_{dt+1})$ as a function of $s_{ct}(= 1 - s_{dt})$. We next claim that this equation has an interior solution $s_{ct+1} \in (0, 1)$ when $s_{ct} \in (0, 1)$ (i.e., when s_{ct} is itself interior). First, note that when $\varphi > 0$ (that is, $\varepsilon < 1$), the function $z(x) = x^{1/(\varphi+1)} - x$ is strictly decreasing for $x < 1$ and strictly increasing for $x > 1$. Therefore, $x = 1$ is the unique positive solution to $z(x) = 0$. Second, note also that the function

$$X(s_{ct}) = \frac{1 + \gamma\eta_c s_{ct}}{1 + \gamma\eta_d s_{dt}} = \frac{1 + \gamma\eta_c s_{ct}}{1 + \gamma\eta_d(1 - s_{ct})},$$

is a one-to-one mapping from $(0, 1)$ onto $((1 + \gamma\eta_d)^{-1}, 1 + \gamma\eta_c)$. Finally, it can be verified that whenever $X \in ((1 + \gamma\eta_d)^{-1}, 1 + \gamma\eta_c)$, we also have $X^{1/(\varphi+1)} \in ((1 + \gamma\eta_d)^{-1}, 1 + \gamma\eta_c)$. This, together with (B.1), implies that if $s_{ct} \in (0, 1)$, then $s_{ct+1} = X^{-1}(X(s_{ct})^{1/(\varphi+1)}) \in (0, 1)$, proving the claim at the beginning of this paragraph.

From Appendix A, when $\varphi > 0$, the equilibrium allocation of scientists is unique at each t . Thus as $t \rightarrow \infty$, this allocation must converge to the unique fixed point of the function $Z(s) = X^{-1} \circ (X(s))^{1/(\varphi+1)}$, which is

$$s_c = \frac{\eta_d}{\eta_c + \eta_d}.$$

This completes the proof of the lemma. ■

Now given the characterization of the equilibrium allocations of scientists in Appendix A, under Assumption 1 the equilibrium involves $s_{dt} = 0$ and $s_{ct} = 1$, i.e., innovation occurs initially in the clean sector only. From (11), A_{ct}/A_{dt} will grow at a rate $\gamma\eta_c$, and in finite time, it will exceed the threshold $(1 + \gamma\eta_c)^{-(\varphi+1)/\varphi} (\eta_c/\eta_d)^{1/\varphi}$. Lemma 2 implies that when this ratio is in the interval $\left((1 + \gamma\eta_c)^{-(\varphi+1)/\varphi} (\eta_c/\eta_d)^{1/\varphi}, (\eta_c/\eta_d)^{1/\varphi} (1 + \gamma\eta_d)^{(\varphi+1)/\varphi} (\eta_c/\eta_d)^{1/\varphi} \right)$, equilibrium innovation occurs in both sectors, i.e., $s_{dt} > 0$ and $s_{ct} > 0$, and from this point onwards, innovation will occur in both sectors and the share of scientists devoted to the clean sector converges to $\eta_d/(\eta_d + \eta_c)$. This completes the proof of Proposition 10.

Speed of disaster in laissez-faire

From the expressions in (19), dirty input production is given by:

$$Y_{dt} = (A_{ct}^\varphi + A_{dt}^\varphi)^{-\frac{\alpha+\varphi}{\varphi}} A_{ct}^{\alpha+\varphi} A_{dt} = \frac{A_{dt}}{\left(1 + \left(\frac{A_{dt}}{A_{ct}}\right)^\varphi\right)^{\frac{\alpha+\varphi}{\varphi}}}.$$

When the two inputs are gross substitutes ($\varepsilon < 1$), we have $\varphi = \varphi^{su} < 0$, whereas when they are complements ($\varepsilon > 1$), we have $\varphi = \varphi^{co} > 0$. Since all innovations occur in the dirty sector in the substitutability case, but not in the complementarity case, if we start with the same levels of technologies in both cases, at any time $t > 0$ we have $A_{dt}^{su} > A_{dt}^{co}$ and $A_{ct}^{su} < A_{ct}^{co}$, where A_{kt}^{su} and A_{kt}^{co} denote the average productivities in sector k at time t respectively in the substitutability and in the complementarity case, starting from the same initial productivities $A_{k0}^{su} = A_{k0}^{co}$.

Assumption 1 implies that

$$\left(\frac{A_{dt}^{su}}{A_{ct}^{su}}\right)^{\varphi^{su}} < \frac{\eta_d}{\eta_c} \leq \left(\frac{A_{dt}^{co}}{A_{ct}^{co}}\right)^{\varphi^{co}}$$

so that

$$\begin{aligned} Y_{dt}^{su} &= \frac{A_{dt}^{su}}{\left(1 + \left(\frac{A_{dt}^{su}}{A_{ct}^{su}}\right)^{\varphi^{su}}\right)^{\frac{\alpha}{\varphi^{su}}+1}} > \frac{A_{ct}^{su}}{\left(1 + \left(\frac{A_{ct}^{co}}{A_{dt}^{co}}\right)^{\varphi^{co}}\right)} \left(1 + \left(\frac{A_{dt}^{su}}{A_{ct}^{su}}\right)^{\varphi^{su}}\right)^{-\frac{\alpha}{\varphi^{su}}} \\ &> \frac{A_{ct}^{su}}{\left(1 + \left(\frac{A_{ct}^{co}}{A_{dt}^{co}}\right)^{\varphi^{co}}\right)} > \frac{A_{ct}^{su}}{\left(1 + \left(\frac{A_{ct}^{co}}{A_{dt}^{co}}\right)^{\varphi^{co}}\right)^{\frac{\alpha}{\varphi^{co}}+1}} > Y_{dt}^{co}. \end{aligned}$$

Repeating the same argument for $t + 1, t + 2, \dots$, we have that $Y_{dt}^{su} > Y_{dt}^{co}$ for all t . This establishes that, under Assumption 1, there will be a greater amount of dirty input production for each t when $\varepsilon > 1$ than when $\varepsilon < 1$, implying that an environmental disaster will occur sooner when the two sectors are gross substitutes.

Proof of Proposition 4

Using the fact that the term $\Omega(S_t)$ premultiplies all A 's, equation (19) must now be replaced by:

$$Y_{dt} = \Omega(S_t)^{\frac{1}{1-\alpha}} (A_{ct}^\varphi + A_{dt}^\varphi)^{-\frac{\alpha+\varphi}{\varphi}} A_{ct}^{\alpha+\varphi} A_{dt}, \text{ and } Y_t = \Omega(S_t)^{\frac{1}{1-\alpha}} (A_{ct}^\varphi + A_{dt}^\varphi)^{-\frac{1}{\varphi}} A_{ct} A_{dt}.$$

In particular, as in Section 3, under laissez-faire all technological progress keeps being directed towards dirty innovation, therefore A_{dt} grows to infinity. Then, a necessary condition for avoiding a disaster under laissez-faire is that Y_{dt} remains bounded above over time, which can only be the case if $\Omega(S_t)^{1/(1-\alpha)} A_{dt}$ also remains bounded. Since A_{dt} is growing exponentially, this is only possible if S_t converges to 0. Now, suppose that $\Omega(S_t)^{1/(1-\alpha)} A_{dt}$ converges to a finite and positive value as time t goes to infinity. Then there exists a constant η such that for any T there is a $\tau > T$ such that $\Omega(S_\tau)^{1/(1-\alpha)} A_{d\tau} > \eta/\xi$. But for $\tau > T$ sufficiently high, we also have $\left| Y_{d\tau} - \Omega(S_\tau)^{1/(1-\alpha)} A_{d\tau} \right| < \eta/(3\xi)$ since $Y_{dt} \simeq \Omega(S_t)^{1/(1-\alpha)} A_{dt}$ asymptotically, and $(1+\delta)S_\tau < \eta/3$ since S_t converges to 0. But then (12) gives $S_{\tau+1} = 0$, which corresponds to an environmental disaster. Consequently, to avoid a disaster under laissez-faire, it must be the case that $\Omega(S_t)^{1/(1-\alpha)} A_{dt}$ converges to 0. But this implies that Y_t converges to 0 as well, and so does C_t . ■

B.1 Proof of Proposition 6

First we need to derive the optimal production of inputs given technologies and the tax implemented. Using (A.38) and (A.39), the shadow values of clean and dirty inputs satisfy

$$\widehat{p}_{ct}^{1-\varepsilon} + (\widehat{p}_{dt} (1 + \tau_t))^{1-\varepsilon} = 1. \quad (\text{B.2})$$

This, together with (A.44), yields

$$\widehat{p}_{dt} = \frac{A_{ct}^{1-\alpha}}{\left(A_{ct}^\varphi (1 + \tau_t)^{1-\varepsilon} + A_{dt}^\varphi \right)^{\frac{1}{1-\varepsilon}}} \text{ and } \widehat{p}_{ct} = \frac{A_{dt}^{1-\alpha}}{\left(A_{ct}^\varphi (1 + \tau_t)^{1-\varepsilon} + A_{dt}^\varphi \right)^{\frac{1}{1-\varepsilon}}}. \quad (\text{B.3})$$

Using (7), (A.41), (A.45) and (B.3), we obtain

$$Y_{ct} = \left(\frac{\alpha}{\psi} \right)^{\frac{\alpha}{1-\alpha}} \frac{(1 + \tau_t)^\varepsilon A_{ct} A_{dt}^{\alpha+\varphi}}{\left(A_{dt}^\varphi + (1 + \tau_t)^{1-\varepsilon} A_{ct}^\varphi \right)^{\frac{\alpha}{\varphi}} \left(A_{ct}^\varphi + (1 + \tau_t)^\varepsilon A_{dt}^\varphi \right)}, \text{ and} \quad (\text{B.4})$$

$$Y_{dt} = \left(\frac{\alpha}{\psi} \right)^{\frac{\alpha}{1-\alpha}} \frac{A_{ct}^{\alpha+\varphi} A_{dt}}{\left(A_{dt}^\varphi + (1 + \tau_t)^{1-\varepsilon} A_{ct}^\varphi \right)^{\frac{\alpha}{\varphi}} \left(A_{ct}^\varphi + (1 + \tau_t)^\varepsilon A_{dt}^\varphi \right)}. \quad (\text{B.5})$$

Equation (B.5) implies that the production of dirty input is decreasing in τ_t . Moreover, clearly as $\tau_t \rightarrow \infty$, we have $Y_{dt} \rightarrow 0$.

We next characterize the behavior of this tax rate and the research subsidy, q_t . Recall that to avoid an environmental disaster, the optimal policy must always ensure that Y_{dt} remained bounded, in particular, $Y_{dt} \leq (1 + \delta)\bar{S}/\xi$.

Assume $\varepsilon > 1$. The proof consists of six parts: (1) We show that, for a discount rate ρ sufficiently low, the optimal allocation cannot feature a bounded Y_{ct} , thus Y_{ct} must become unbounded as t goes to infinity. (2) We show that this implies that A_{ct} must tend towards infinity. (3) We show that if the optimal allocation involves Y_{ct} unbounded (i.e $\limsup Y_{ct} = \infty$), then it must be the case that at the optimum $Y_{ct} \rightarrow \infty$ as t goes to infinity. (4) We prove that the economy switches towards clean research, that is, $s_{ct} \rightarrow 1$. (5) We prove that the switch in research to clean technologies occurs in finite time, that is, there exists \tilde{T} such that $s_{ct} = 1$ for all $t \geq \tilde{T}$. (6) We then derive the implied behavior of τ_t and q_t .

Part 1: To obtain a contradiction, suppose that the optimal allocation features Y_{ct} remaining bounded as t goes to infinity. If Y_{dt} was unbounded, then there would be an environmental disaster, but then the allocation could not be optimal in view of the assumption that $\lim_{S \downarrow 0} u(C, S) = -\infty$ (equation (2)). Thus Y_{dt} must also remain bounded as t goes to infinity. But if both Y_{ct} and Y_{dt} remain bounded, so will Y_t and C_t . We use the superscript ns (ns for “no switch”) to denote the variables under this allocation.

Consider an alternative (feasible) allocation, featuring all research being directed to clean technologies after some date \hat{t} , i.e., $s_{ct} = 1$ for all $t > \hat{t}$ and no production of dirty input (by taking an infinite carbon tax τ_t). This in turn implies that S_t reaches \bar{S} in finite time because of regeneration at the rate δ in (12). Moreover, (B.4) implies that $Y_t/A_{ct} \rightarrow \text{constant}$ and thus $C_t/A_{ct} \rightarrow \text{constant}$. Let us use superscript a to denote all variables under this alternative allocation. Then there exists a consumption level $\bar{C} < \infty$, and a date $T < \infty$ such that for $t \geq T$, $C_t^{ns} < \bar{C}$, $C_t^a > \bar{C} + \theta$ (where $\theta > 0$) and $S_t^a = \bar{S}$. Now using the fact that u is strictly increasing in C and S , for all $t \geq T$ we have

$$u(C_t^a, S_t^a) - u(C_t^{ns}, S_t^{ns}) \geq u(C_t^a, \bar{S}) - u(\bar{C}, \bar{S}) > 0$$

which is positive and strictly increasing over time. Then the welfare difference between the alternative and the no-switch allocations can be written as

$$\begin{aligned} W^a - W^{ns} &= \sum_{t=0}^{T-1} \frac{1}{(1+\rho)^t} (u(C_t^a, S_t^a) - u(C_t^{ns}, S_t^{ns})) + \sum_{t=T}^{\infty} \frac{1}{(1+\rho)^t} (u(C_t^a, S_t^a) - u(C_t^{ns}, S_t^{ns})) \\ &\geq \sum_{t=0}^{T-1} \frac{1}{(1+\rho)^t} (u(C_t^a, S_t^a) - u(C_t^{ns}, S_t^{ns})) + \frac{1}{(1+\rho)^T} \sum_{t=T}^{\infty} \frac{1}{(1+\rho)^{t-T}} (u(C_t^a, \bar{S}) - u(\bar{C}, \bar{S})). \end{aligned}$$

Since the utility function is continuous in C , and C_t^{ns} is finite for all $t < T$ (for all ρ), then as ρ decreases the first term remains bounded above by a constant, while the second term tends to infinity. This establishes that $W^a - W^{ns} > 0$ for ρ sufficiently small, yielding a contradiction and establishing that we must have Y_{ct} unbounded when t goes to infinity.

Part 2: Now (B.4) directly implies that

$$A_{ct} \geq g(Y_{ct}) = \left(\frac{\alpha}{\psi}\right)^{\frac{-\alpha}{1-\alpha}} Y_{ct} \left(1 + \left(\frac{Y_{ct}}{M}\right)^{\frac{1-\varepsilon}{\varepsilon}}\right)^{\frac{\alpha}{\varphi}}$$

where M is an upper-bound on Y_{dt} . g is an increasing function and $\limsup Y_{ct} = \infty$, so $\limsup A_{ct} = \infty$ and as A_{ct} is weakly increasing, $\lim A_{ct} = \infty$.

Part 3: Now suppose by contradiction that $\liminf Y_{ct} \neq \infty$, then by definition it must be the case that $\exists M'$ such that $\forall T, \exists t > T$ with $Y_{ct} < M'$. Let us consider such an M' and note that we can always choose it to be higher than the upper bound on Y_{dt} . Then we can define a subsequence t_n with $t_n \geq n$ and $Y_{ct_n} < M'$ for all n . Since $Y_{dt} < M'$ as well, we have that for all n : $C_{t_n} < Y_{t_n} < 2^{\varepsilon/(\varepsilon-1)} M'$. Moreover, since $\lim_{t \rightarrow \infty} A_{ct} = \infty$, there exists an integer θ such that for any $t > \theta$, $A_{ct} > (\alpha/\psi)^{-\alpha/(1-\alpha)} 2^{\varepsilon/(\varepsilon-1)} M' / (1-\alpha)$. Consequently, for $n \geq \theta$ we have: $C_{t_n} < Y_{t_n} < 2^{\varepsilon/(\varepsilon-1)} M'$ and $A_{ct_n} > (\alpha/\psi)^{-\alpha/(1-\alpha)} 2^{\varepsilon/(\varepsilon-1)} M' / (1-\alpha)$.

Consider now the alternative policy that mimics the initial policy, except that in all periods t_n for $n \geq \theta$ the social planner chooses the carbon tax $\tau_{t_n}^a$ to be sufficiently large (the superscript a designates ‘‘alternative’’) that $Y_{dt_n}^a = 0$. Then we have: $Y_{t_n}^a = Y_{ct_n}^a = (\alpha/\psi)^{\alpha/(1-\alpha)} A_{ct_n}$, which yields $S_t^a \geq S_t$ for all $t \geq t_n$ since the alternative policy either reduces or maintains dirty input production relative to the original policy. Moreover, we have: $C_{t_n}^a = (1-\alpha)Y_{t_n}^a \geq (1-\alpha)(\alpha/\psi)^{\alpha/(1-\alpha)} A_{ct_n} > 2^{\varepsilon/(\varepsilon-1)} M' > C_{t_n}$, whereas consumption in periods $t \neq t_n$ remains unchanged. Thus the alternative policy leads to (weakly) higher consumption and environmental quality in all periods, and to strictly higher consumption in periods $t = t_n$, thus overall to strictly higher welfare, than the original policy. Hence the original policy is not optimal, using a contradiction. This in turn establishes that on the optimal path $\liminf Y_{ct} = \infty$ and therefore $\lim Y_{ct} = \infty$.

Part 4: From Part 3 we know that on the optimal path $Y_{ct}/Y_{dt} \rightarrow \infty$, that is $(1 + \tau_t)^{1-\varepsilon} (A_{ct}/A_{dt})^\varphi \rightarrow 0$. Now from (B.4) and (B.5), one can reexpress consumption as a function of the carbon tax and technologies:

$$C_t = \left(\frac{\alpha}{\psi}\right)^{\frac{-\alpha}{1-\alpha}} \frac{A_{ct} A_{dt}}{\left((1 + \tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi\right)^{\frac{1}{\varphi}}} \left(1 - \alpha + \frac{\tau_t A_{ct}^\varphi}{A_{ct}^\varphi + (1 + \tau_t)^\varepsilon A_{dt}^\varphi}\right); \quad (\text{B.6})$$

Since $(1 + \tau_t) (A_{ct}/A_{dt})^{1-\alpha} \rightarrow \infty$, we get

$$\lim \frac{C_t}{A_{ct}} = \left(\frac{\alpha}{\psi}\right)^{\frac{-\alpha}{1-\alpha}} (1 - \alpha)$$

Now by contradiction let us suppose that $\liminf s_{ct} = s < 1$. Then for any \tilde{T} there exists $\theta > \tilde{T}$, such that $s_{ct} < (1 + s)/2$. Now, as $\lim(C_t/A_{ct}) = (\alpha/\psi)^{\alpha/(1-\alpha)} (1 - \alpha)$, there exists some T such that for any $t > T$, we have $C_t < (\alpha/\psi)^{\alpha/(1-\alpha)} (1 - \alpha) A_{ct} (1 + \gamma\eta_c) / (1 + \gamma\eta_c (1 + s)/2)$.

Then take θ sufficiently large that $\theta > T$ and $s_{c\theta} < (1+s)/2$, and consider the following alternative policy: the alternative policy is identical to the original policy up to time $\theta-1$, then at θ , the alternative policy allocates all research to the clean sector, and for $t > \theta$, the allocation of research is identical to the original policy, and for $t \geq \theta$, the carbon tax is infinite. Then under the alternative policy, there is no pollution for $t \geq \theta$ so the quality of the environment is weakly better than under the original policy. Moreover: $A_{ct}^a = (1 + \gamma\eta_c) A_{ct} / (1 + \gamma\eta_c s_{c\theta})$, for all $t \geq \theta$ (where the superscript a indicates the alternative policy schedule). Thus for $t \geq \theta$:

$$\begin{aligned} C_t^a &= \left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}} (1-\alpha) A_{ct}^a > \left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}} (1-\alpha) \frac{1+\gamma\eta_c}{1+\gamma\eta_c s_{c\theta}} A_{ct} \\ &> \left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}} (1-\alpha) \frac{1+\gamma\eta_c}{1+\gamma\eta_c \left(\frac{1+s}{2}\right)} A_{ct} > C_t, \end{aligned}$$

so that the alternative policy brings higher welfare. This in turn contradicts the optimality of the original policy. Hence $\liminf s_{ct} = 1$, so $\lim s_{ct} = 1$, and consequently, $\lim(A_{ct}^\varphi/A_{dt}^\varphi) = 0$.

Part 5: First note that (B.5) and (B.6) can be rewritten as:

$$\ln(C_t) - \ln\left(\left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}}\right) = \ln(A_{ct}) + \ln(A_{dt}) - \frac{1}{\varphi} \ln\left(\left((1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi\right)\right) + \ln\left(1 - \alpha + \frac{\tau_t A_{ct}^\varphi}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi}\right), \quad (\text{B.7})$$

$$\ln(Y_{dt}) - \ln\left(\left(\frac{\alpha}{\psi}\right)^{\frac{\alpha}{1-\alpha}}\right) = (\alpha + \varphi) \ln(A_{ct}) + \ln(A_{dt}) - \frac{\alpha}{\varphi} \ln\left(\left(A_{dt}^\varphi + (1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi\right)\right) - \ln\left(\left(A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi\right)\right) \quad (\text{B.8})$$

Now, suppose that s_{ct} does not reach 1 in finite time. Then for any T , there exists $\theta > T$, such that $s_{c\theta} < 1$. For T arbitrarily large $s_{c\theta}$ becomes arbitrarily close to 1, so that $1 - s_{c\theta}$ becomes infinitesimal and is accordingly denoted ds . We then consider the following thought experiment: let us increase the allocation of researchers to clean innovation at θ from $s_{c\theta} < 1$ to 1, but leave this allocation unchanged in all subsequent periods. Meanwhile, let us adjust the tax τ_t in all periods after θ in order to leave Y_{dt} unchanged. Then using superscript a to denote the value of technologies under the alternative policy, we have for $t \geq \theta$:

$$A_{ct}^a = \frac{1 + \gamma\eta_c}{1 + \gamma\eta_c s_{c\theta}} A_{ct}.$$

A first-order Taylor expansion of the logarithm of the productivity around $s_{c\theta} = 1$ yields:

$$d(\ln(A_{ct})) = \frac{\gamma\eta_c ds}{1 + \gamma\eta_c} + o(ds), \quad (\text{B.9})$$

and similarly,

$$d(\ln(A_{dt})) = -\gamma\eta_d ds + o(ds).$$

Using the fact that that $d(\ln(A_{ct}))$ and $d(\ln(A_{dt}))$ are of the same order as ds , first-order Taylor expansions of (B.7) and (B.8) give:

$$\begin{aligned}
& d(\ln(C_t)) \tag{B.10} \\
= & d(\ln(A_{ct})) + d(\ln(A_{dt})) - \frac{(1+\tau)^{1-\varepsilon} A_{ct}^\varphi (\varphi d(\ln(A_{ct})) + (1-\varepsilon) d(\ln(1+\tau_t))) + \varphi A_{dt}^\varphi d(\ln(A_{dt}))}{\varphi \left((1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi \right)} \\
& + \frac{1}{1-\alpha + \frac{\tau_t A_{ct}^\varphi}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi}} \frac{(1+\tau_t) A_{ct}^\varphi d(\ln(1+\tau_t)) + \varphi \tau_t A_{ct}^\varphi d(\ln(A_{ct}))}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi} \\
& - \frac{\tau_t A_{ct}^\varphi}{1-\alpha + \frac{\tau_t A_{ct}^\varphi}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi}} \frac{\varphi A_{ct}^\varphi d(\ln(A_{ct})) + (1+\tau_t)^\varepsilon A_{dt}^\varphi (\varphi d(\ln(A_{dt})) + \varepsilon d(\ln(1+\tau_t)))}{(A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi)^2} \\
& + o(ds) + o(d(\ln(1+\tau_t))),
\end{aligned}$$

and

$$\begin{aligned}
d(\ln(Y_{dt})) &= (\alpha + \varphi) d(\ln(A_{ct})) + d(\ln(A_{dt})) \\
& - \frac{(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi (\varphi d(\ln(A_{ct})) + (1-\varepsilon) d(\ln(1+\tau_t))) + \varphi A_{dt}^\varphi d(\ln(A_{dt}))}{\varphi \alpha^{-1} \left((1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi \right)} \\
& - \frac{\varphi A_{ct}^\varphi d(\ln(A_{ct})) + (1+\tau_t)^\varepsilon A_{dt}^\varphi (\varphi d(\ln(A_{dt})) + \varepsilon d(\ln(1+\tau_t)))}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi} + o(ds) + o(d(\ln(1+\tau_t))).
\end{aligned}$$

Then, using the fact that in the variation in question, taxes are adjusted to keep production of the dirty input constant, the previous equation gives:

$$\begin{aligned}
& \left(\frac{\varepsilon (1+\tau_t)^\varepsilon A_d^\varphi}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi} + \frac{\alpha (1-\varepsilon) (1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi}{\varphi (1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi} \right) d(\ln(1+\tau_t)) \\
= & (\alpha + \varphi) d(\ln(A_{ct})) + d(\ln(A_{dt})) - \frac{\alpha \varphi (1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi d(\ln(A_{ct})) + \varphi A_{dt}^\varphi d(\ln(A_{dt}))}{\varphi (1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi} \\
& - \frac{\varphi A_{ct}^\varphi d(\ln(A_{ct})) + \varphi (1+\tau_t)^\varepsilon A_{dt}^\varphi d(\ln(A_{dt}))}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi} + o(ds) + o(d(\ln(1+\tau_t))).
\end{aligned}$$

Now recall the following: (i) $\lim_{t \rightarrow \infty} A_{ct}^\varphi / A_{dt}^\varphi = 0$; (ii) the term $\frac{\varepsilon(1+\tau_t)^\varepsilon A_d^\varphi}{A_{ct}^\varphi + (1+\tau_t)^\varepsilon A_{dt}^\varphi} + \frac{\alpha(1-\varepsilon)(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi}{\varphi(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi + A_{dt}^\varphi}$ is bounded and bounded away from 0; (iii) the terms in front of $d(\ln(A_{dt}))$ and $d(\ln(A_{ct}))$ are bounded. Therefore, we can rewrite (B.10) as:

$$\begin{aligned}
d(\ln(C_t)) &= d(\ln(A_{ct})) + \frac{(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi}}{(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi} + 1} \left(d(\ln(A_{dt})) - d(\ln(A_{ct})) - (1-\alpha)^{-1} d(\ln(1+\tau_t)) \right) \\
& + \frac{1}{1-\alpha + \frac{\tau_t(1+\tau_t)^{-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi}}{A_{ct}^\varphi A_{dt}^{-\varphi} (1+\tau_t)^{-\varepsilon} + 1}} \frac{(1+\tau_t)^{1-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi}}{(1+\tau_t)^{-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi} + 1} \left(d(\ln(1+\tau_t)) + \varphi \frac{\tau_t}{1+\tau_t} d(\ln(A_{ct})) \right) \\
& - \frac{\tau_t (1+\tau_t)^{-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi}}{1-\alpha + \frac{\tau_t(1+\tau_t)^{-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi}}{A_{ct}^\varphi A_{dt}^{-\varphi} (1+\tau_t)^{-\varepsilon} + 1}} \frac{\varphi A_{ct}^\varphi A_{dt}^{-\varphi} (1+\tau_t)^{-\varepsilon} d(\ln(A_{ct})) + \varphi d(\ln(A_{dt})) + \varepsilon d(\ln(1+\tau_t))}{\left((1+\tau_t)^{-\varepsilon} A_{ct}^\varphi A_{dt}^{-\varphi} + 1 \right)^2} + o(ds)
\end{aligned}$$

Using again the fact that $\lim_{t \rightarrow \infty} A_{ct}^\varphi/A_{dt}^\varphi = 0$ and (B.9), the previous expression becomes

$$d(\ln(C_t)) = \left(\frac{\gamma\eta_c}{1 + \gamma\eta_c} + O\left(\frac{A_{ct}^\varphi}{A_{dt}^\varphi}\right) \right) ds + o(ds),$$

which implies that for T sufficiently large, $O(A_{ct}^\varphi/A_{dt}^\varphi)$ will be smaller than $\gamma\eta_c/(1 + \gamma\eta_c)$, and thus consumption increases. This implies that the alternative policy raises consumption for all periods after θ , and does so without affecting the quality of the environment, hence the original policy cannot be optimal. This contradiction establishes that s_{ct} reaches 1 in finite time.

Part 6: Thus the optimal allocation must involve $s_{ct} = 1$ for all $t \geq \tilde{T}$ (for some $\tilde{T} < \infty$) and $A_{ct}/A_{dt} \rightarrow \infty$. Then, note that (A.46) implies that even if $\tau_t = q_t = 0$, the equilibrium allocation of scientists involves $s_{ct} = 1$ for all $t \geq T$ for some T sufficiently large. This is sufficient to establish that $q_t = 0$ for all $t \geq T$ is consistent with an optimal allocation. Finally, equation (B.5) implies that when $\varepsilon > 1/(1 - \alpha)$, $Y_{dt} \rightarrow 0$, which together with (12), implies that S_t reaches \bar{S} in finite time. But then the assumption that $\partial u(C, \bar{S})/\partial S = 0$ combined with (23) implies that the optimal input tax reaches 0 in finite time. On the contrary, when $\varepsilon \leq 1/(1 - \alpha)$, even when all research ends up being directed towards clean technologies, (B.5) shows that without imposing a positive input tax we have $Y_{dt} \rightarrow \infty$ and thus $S_t = 0$ in finite time, which cannot be optimal. So in this case, taxation must be permanent at the optimum.

Equilibrium profit ratio with exhaustible resources

We first analyze how the static equilibrium changes when we introduce the limited resource constraint. The description of clean sectors remains exactly as before. Profit maximization by producers of machines in the dirty sector now leads to the equilibrium price $p_{dit} = \psi/\alpha_1$ (as α_1 is the share of machines in the production of dirty input). The equilibrium output level for machines is then given by:

$$x_{dit} = \left((\alpha_1)^2 \psi^{-1} p_{dt} R_t^{\alpha_2} L_{dt}^{1-\alpha} \right)^{\frac{1}{1-\alpha_1}} A_{dit}. \quad (\text{B.11})$$

Profit maximization by the dirty input producer leads to the following demand equation for the resource: $p_{dt} \alpha_2 R_t^{\alpha_2-1} L_{dt}^{1-\alpha} \int_0^1 A_{dit}^{1-\alpha_1} x_{dit}^{\alpha_1} di = c(Q_t)$, plugging in the equilibrium output level of machines (B.11) yields:

$$R_t = \left(\frac{(\alpha_1)^2}{\psi} \right)^{\frac{\alpha_1}{1-\alpha}} \left(\frac{\alpha_2 A_{dt}}{c(Q_t)} \right)^{\frac{1-\alpha_1}{1-\alpha}} p_{dt}^{\frac{1}{1-\alpha}} L_{dt} \quad (\text{B.12})$$

which in turn, together with (5), leads to the following expression for the equilibrium production of dirty input:

$$Y_{dt} = \left(\frac{(\alpha_1)^2}{\psi} \right)^{\frac{\alpha_1}{1-\alpha}} \left(\frac{\alpha_2 A_{dt}}{c(Q_t)} \right)^{\frac{\alpha_2}{1-\alpha}} p_{dt}^{\frac{\alpha}{1-\alpha}} L_{dt} A_{dt}, \quad (\text{B.13})$$

while equilibrium profits from producing machine i in the dirty sector becomes:

$$\pi_{dit} = (1 - \alpha_1) \alpha_1^{\frac{1+\alpha_1}{1-\alpha_1}} \left(\frac{1}{\psi^{\alpha_1}} \right)^{\frac{1}{1-\alpha_1}} p_{dt}^{\frac{1}{1-\alpha_1}} R_t^{\frac{\alpha_2}{1-\alpha_1}} L_{dt}^{\frac{1-\alpha}{1-\alpha_1}} A_{dit}. \quad (\text{B.14})$$

The production of the clean input and the profits of the producer of machine i in the clean sector are still given by (A.33) and (15). Now, labor market clearing requires that the marginal product of labor be equalized across sectors; this, together with (B.13) and (A.33) for $j = c$, leads to the equilibrium price ratio:

$$\frac{p_{ct}}{p_{dt}} = \frac{\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} A_{dt}^{1-\alpha_1}}{c(Q_t)^{\alpha_2} \alpha^{2\alpha} A_{ct}^{1-\alpha}}, \quad (\text{B.15})$$

thus a higher extraction cost will bid up the price of the dirty input. Profit maximization by final good producers still yields (13) which, together with (B.15), (B.13) and (A.33) for $j = c$, yield the relative employment in the two sectors:

$$\frac{L_{ct}}{L_{dt}} = \left(\frac{c(Q_t)^{\alpha_2} \alpha^{2\alpha}}{\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2}} \right)^{(\varepsilon-1)} \frac{A_{ct}^{-\varphi}}{A_{dt}^{-\varphi_1}}, \quad (\text{B.16})$$

with $\varphi_1 \equiv (1 - \alpha_1)(1 - \varepsilon)$. Hence, the higher the extraction cost, the higher the amount of labor allocated to the clean industry when $\varepsilon > 1$.

Using (15) for $j = c$, (B.14), (B.12), (B.15), (B.16), the ratio of expected profits from undertaking innovation at time t in the clean versus the dirty sector, is then equal to:

$$\begin{aligned} \frac{\Pi_{ct}}{\Pi_{dt}} &= \frac{\eta_c (1 - \alpha_1) \alpha_1^{\frac{1+\alpha_1}{1-\alpha_1}} \left(\frac{1}{\psi^{\alpha_1}} \right)^{\frac{1}{1-\alpha_1}} p_{ct}^{\frac{1}{1-\alpha}} L_{ct}}{\eta_d (1 - \alpha) \alpha^{\frac{1+\alpha}{1-\alpha}} \left(\frac{1}{\psi} \right)^{\frac{\alpha}{1-\alpha}} p_{dt}^{\frac{1}{1-\alpha_1}} R_t^{\frac{\alpha_2}{1-\alpha_1}} L_{dt}^{\frac{1-\alpha}{1-\alpha_1}} A_{dt-1}} \frac{A_{ct-1}}{A_{dt-1}} \\ &= \kappa \frac{\eta_c c(Q_t)^{\alpha_2(\varepsilon-1)} (1 + \gamma \eta_c s_{ct})^{-\varphi-1} A_{ct-1}^{-\varphi}}{\eta_d (1 + \gamma \eta_d s_{dt})^{-\varphi_1-1} A_{dt-1}^{-\varphi_1}} \end{aligned}$$

where we let $\kappa \equiv \frac{(1-\alpha)\alpha}{(1-\alpha_1)\alpha_1^{\frac{1+\alpha_1}{1-\alpha_1}} \left(\frac{1}{\psi^{\alpha_1}} \right)^{\frac{1}{1-\alpha_1}} \left(\frac{\alpha^{2\alpha}}{\psi^{\alpha_2} \alpha_1^{2\alpha_1} \alpha_2^{\alpha_2}} \right)^{(\varepsilon-1)}}$. This establishes (25). \blacksquare

Proof of Proposition 7

First, we derive the equilibrium production of R_t and Y_{dt} .

Using the expression for the equilibrium price ratio (B.15), together with the choice of the final good as the numeraire (9), we get:

$$p_{ct} = \frac{\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} A_{dt}^{1-\alpha_1}}{\left((\alpha^{2\alpha} c(Q_t)^{\alpha_2})^{1-\varepsilon} A_{ct}^{\varphi} + \left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{1-\varepsilon} A_{dt}^{\varphi_1} \right)^{\frac{1}{1-\varepsilon}}}$$

$$p_{dt} = \frac{\alpha^{2\alpha} (c(Q_t))^{\alpha_2} A_{ct}^{1-\alpha}}{\left((\alpha^{2\alpha} c(Q_t)^{\alpha_2})^{1-\varepsilon} A_{ct}^\varphi + \left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{1-\varepsilon} A_{dt}^{\varphi_1} \right)^{\frac{1}{1-\varepsilon}}}$$

Similarly, using the expression for the equilibrium labor ratio (B.16), and labor market clearing (7), we obtain:

$$L_{dt} = \frac{(c(Q_t)^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi}{(c(Q_t)^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi + \left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{(1-\varepsilon)} A_{dt}^{\varphi_1}}$$

$$L_{ct} = \frac{\left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{(1-\varepsilon)} A_{dt}^{\varphi_1}}{(c(Q_t)^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi + \left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{(1-\varepsilon)} A_{dt}^{\varphi_1}}$$

Next, using the above expressions for equilibrium prices and labor allocation, and plugging them in (B.12) and (B.13), we obtain:

$$Y_{dt} = \frac{\left(\frac{\alpha_1^2}{\psi} \right)^{\frac{\alpha_1}{1-\alpha}} \alpha_2^{\frac{\alpha_2}{1-\alpha}} \alpha^{2\alpha \left(\frac{1}{1-\alpha} - \varepsilon \right)} c(Q_t)^{-\varepsilon \alpha_2} A_{ct}^{\alpha+\varphi} A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}}{\left((c(Q_t)^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi + \left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{(1-\varepsilon)} A_{dt}^{\varphi_1} \right)^{\frac{\alpha+\varphi}{\varphi}}} \quad (\text{B.17})$$

and

$$R_t = \frac{\alpha^{2\alpha \left(\frac{1}{1-\alpha} + 1 - \varepsilon \right)} \alpha_1^{2 \frac{\alpha_1}{1-\alpha}} \alpha_2^{\frac{1-\alpha_1}{1-\alpha}} \psi^{-\frac{\alpha_1}{1-\alpha}} (c(Q_t))^{\alpha_2 - 1 - \alpha_2 \varepsilon} A_{ct}^{1+\varphi} A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}}{\left((c(Q_t)^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi + \left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{(1-\varepsilon)} A_{dt}^{\varphi_1} \right)^{\frac{1+\varphi}{\varphi}}},$$

so that the ratio of resource consumed per unit of dirty input is:

$$\frac{R_t}{Y_{dt}} = \frac{\alpha_2 \alpha^{2\alpha} (c(Q_t))^{\alpha_2 - 1}}{\left((\alpha^{2\alpha} c(Q_t)^{\alpha_2})^{1-\varepsilon} + \left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{1-\varepsilon} \frac{A_{dt}^{\varphi_1}}{A_{ct}^\varphi} \right)^{\frac{1}{1-\varepsilon}}}.$$

When $\varepsilon > 1$, production of the dirty input is not essential to final good production. Thus, even if the stock of exhaustible resource gets fully depleted, it is still possible to achieve positive long-run growth. For a disaster to occur for any initial value of the environmental quality, it is necessary that Y_{dt} grow at a positive rate, while R_t must converge to 0. This implies that R_t/Y_{dt} must converge to 0. This in turn means that the expression

$$\left(\alpha^{2\alpha} c(Q_t)^{\alpha_2} \right)^{1-\varepsilon} + \left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2} \right)^{1-\varepsilon} \frac{A_{dt}^{\varphi_1}}{A_{ct}^\varphi}$$

must converge to zero, which is impossible since $c(Q_t)$ is bounded above. Therefore, for sufficiently high initial quality of the environment, a disaster will be avoided.

Next, one can show that innovation will always end up occurring in the clean sector only. This is obvious if the resource gets depleted in finite time, so let us consider the case where it never gets depleted. The ratio of expected profits in clean versus dirty innovation is given by

$$\frac{\Pi_{ct}}{\Pi_{dt}} = \kappa \frac{\eta_c c(Q_t)^{\alpha_2(\varepsilon-1)} (1 + \gamma\eta_c s_{ct})^{-\varphi-1} A_{ct-1}^{-\varphi}}{\eta_d (1 + \gamma\eta_d s_{dt})^{-\varphi_1-1} A_{dt-1}^{-\varphi_1}},$$

so that to prevent innovation from occurring asymptotically in the clean sector only, it must be the case that $A_{ct}^{-\varphi}$ does not grow faster than $A_{dt}^{-\varphi_1}$. In this case $R = O\left(A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}$). But $A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}$ grows at a positive rate over time, so that the resource gets depleted in finite time after all. This completes the proof of Proposition 7.

The case where $\varepsilon < 1$: It is also straightforward to derive the corresponding results for the case where $\varepsilon < 1$. In particular, when $\varepsilon < 1$, Y_{dt} is now essential for production and thus so is the resource flow R_t . Consequently, it is necessary that Q_t does not get depleted in finite time in order to get positive long-run growth. Recall that innovation takes place in both sectors if and only if $\kappa \frac{\eta_c c(Q_t)^{\alpha_2(\varepsilon-1)} (1 + \gamma\eta_c s_{ct})^{-\varphi-1} A_{ct-1}^{-\varphi}}{\eta_d (1 + \gamma\eta_d s_{dt})^{-\varphi_1-1} A_{dt-1}^{-\varphi_1}} = 1$, and positive long-run growth requires positive growth of both dirty input and clean input productions. This requires that innovation occurs in both sectors, so $A_{dt}^{1-\alpha_1}$ and $A_{ct}^{1-\alpha}$ should be of same order.

But then:

$$R = O\left(A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}\right),$$

so that R_t grows over time. But this in turn leads to the resource stock being fully exhausted in finite time, thereby also shutting down the production of dirty input, which here prevents positive long-run growth. ■

Proof of Proposition 8

We denote the Lagrange multiplier for equation (6) by \tilde{m}_t . We can use (6) to rewrite the condition $Q_t \geq 0$ for all t , as:

$$\sum_{v=0}^{\infty} R_v \leq Q(0).$$

Denoting the Lagrange multiplier for this constraint by $\nu \geq 0$, the first-order condition with respect to R_t gives:

$$\alpha_2 \hat{p}_{dt} R_t^{\alpha_2-1} L_{dt}^{1-\alpha} \int_0^1 A_{dit}^{1-\alpha_1} x_{dit}^{\alpha_1} di = \frac{\tilde{m}_t + \nu}{\lambda_t} + c(Q_t),$$

where recall that $\hat{p}_{jt} = \lambda_{jt}/\lambda_t$. The wedge $(\tilde{m}_t + \nu)/\lambda_t$ is the value, in time t units of final good, of one unit of resource at time t .

The law of motion for the shadow value of one unit of natural resource at time t is then determined by the first-order condition with respect to Q_t , namely

$$\tilde{m}_t = \tilde{m}_{t-1} + \lambda_t c'(Q_t) R_t,$$

where $\tilde{m}_t \geq 0$. Letting $m_t = \tilde{m}_t + \nu$ we obtain:

$$m_t = m_\infty + \sum_{v=t+1}^{\infty} \lambda_v (-c'(Q_v)) R_v,$$

where $m_\infty > 0$ is the limit of m_t as $t \rightarrow \infty$.

Thus achieving the social optimum requires a resource tax equal to

$$\theta_t = \frac{m_t}{\lambda_t c(Q_t)} = \frac{(1 + \rho)^t m_\infty - \sum_{v=t+1}^{\infty} \frac{1}{(1+\rho)^{v-t}} c'(Q_v) R_v \partial u(C_v, S_v) / \partial C}{c(Q_t) \partial u(C_t, S_t) / \partial C}. \quad (\text{B.18})$$

In particular, the optimal resource tax is always positive. ■

Proof of Proposition 9

The proof proceeds in three parts: in Part 1, we prove that when $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma \eta_d)$, then in the long run innovation must occur in the clean sector only. In Part 2, we show that if $\ln(1 + \rho) < [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma \eta_d)$ and innovation occurs in the dirty sector only or in both sectors in the long run, then a disaster necessarily occurs. Finally, in Part 3, we derive the asymptotic growth rate of dirty input production when innovation occurs in the clean sector only.

First, note that the expressions for Y_{jt} , derived above for the case where there are no well-defined property rights to the resource, still hold provided one replaces the unit extraction cost $c(Q_t)$ by the resource price P_t . So that (B.17) now becomes:

$$Y_{dt} = \frac{\left(\frac{\alpha_1^2}{\psi}\right)^{\frac{\alpha_1}{1-\alpha_1}} \alpha_2^{\frac{\alpha_2}{1-\alpha_2}} \alpha^{2\alpha(\frac{1}{1-\alpha} - \varepsilon)} P_t^{-\varepsilon \alpha_2} A_{ct}^{\alpha+\varphi} A_{dt}^{\frac{1-\alpha_1}{1-\alpha}}}{\left((P_t^{\alpha_2} \alpha^{2\alpha})^{(1-\varepsilon)} A_{ct}^\varphi + \left(\psi^{\alpha_2} \alpha_1^{2\alpha_1} (\alpha_2)^{\alpha_2}\right)^{(1-\varepsilon)} A_{dt}^{\varphi_1}\right)^{\frac{\alpha+\varphi}{\varphi}}}, \quad (\text{B.19})$$

similarly we get:

$$Y_{ct} = \frac{\left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2}\right)^{\frac{\alpha+\varphi}{1-\alpha_1}} A_{ct} A_{dt}^{\frac{1-\alpha_1}{1-\alpha}(\alpha+\varphi)}}{\left((\alpha^{2\alpha} P_t^{\alpha_2})^{1-\varepsilon} A_{ct}^\varphi + \left(\psi^{\alpha_2} (\alpha_1)^{2\alpha_1} (\alpha_2)^{\alpha_2}\right)^{1-\varepsilon} A_{dt}^{\varphi_1}\right)^{\frac{\alpha+\varphi}{\varphi}}}, \quad (\text{B.20})$$

and we can rewrite (25) as:

$$\frac{\Pi_{ct}}{\Pi_{dt}} = \kappa \frac{\eta_c}{\eta_d} \frac{P_t^{\alpha_2(\varepsilon-1)} (1 + \gamma \eta_c s_{ct})^{-\varphi-1} A_{ct-1}^{-\varphi}}{(1 + \gamma \eta_d s_{dt})^{-\varphi_1-1} A_{dt-1}^{-\varphi_1}}. \quad (\text{B.21})$$

Part 1: Let us assume that $\ln(1 + \rho) > [(1 - \alpha_1)/\alpha_2] \ln(1 + \gamma\eta_d)$. We want to show that innovation then ends up occurring in the clean sector only in the long run. Here, we shall reason by contradiction, and assume, first that innovation ends up occurring in the dirty sector only in the long run, and second that innovation keeps occurring in both sectors forever, and each time we shall generate a contradiction.

Part 1.a: Assume that innovation ends up occurring in the dirty sector only. Then, from (B.21), the ratio of expected profits from innovating clean to expected profits from innovating dirty, is asymptotically proportional to $\left(P_t^{\alpha_2}/A_{dt}^{1-\alpha_1}\right)^{\varepsilon-1}$, i.e.,

$$\Pi_{ct}/\Pi_{dt} = O\left(P_t^{\alpha_2}/A_{dt}^{1-\alpha_1}\right)^{\varepsilon-1}. \quad (\text{B.22})$$

Thus, for innovation to take place only in the dirty sector in the long run, it is necessary for $A_{dt}^{1-\alpha_1}$ to grow faster than $P_t^{\alpha_2}$. Assume that this is the case, then using (B.19) we obtain

$$Y_{dt} = O\left(A_{dt}^{1-\alpha_1}/P_t^{\alpha_2}\right)^{\frac{1}{1-\alpha}} \quad (\text{B.23})$$

so that the asymptotic growth rate of the economy g satisfies:

$$\ln(1 + g) = \frac{(1 - \alpha_1) \ln(1 + \gamma\eta_d) - \alpha_2 \ln(1 + r)}{(1 - \alpha)}.$$

Combining this with (27) gives:

$$\ln(1 + g) = \frac{(1 - \alpha_1) \ln(1 + \gamma\eta_d) - \alpha_2 \ln(1 + \rho)}{1 - \alpha + \alpha_2\sigma}. \quad (\text{B.24})$$

Since $\ln(1 + \rho) > [(1 - \alpha_1)/\alpha_2] \ln(1 + \gamma\eta_d)$, this equation implies $g < 0$, and therefore the ratio of expected profits Π_{ct}/Π_{dt} goes to infinity over time. Thus innovation only in the dirty sector in the long run cannot be an equilibrium, yielding a contradiction.

Part 1.b: Assume now that innovation occurs in both sectors forever. Using (B.21) we obtain:

$$\Pi_{ct}/\Pi_{dt} = O\left(P_t^{\alpha_2} A_{ct}^{1-\alpha}/A_{dt}^{1-\alpha_1}\right)^{\varepsilon-1},$$

so that $P_t^{\alpha_2} A_{ct}^{1-\alpha}$ and $A_{dt}^{1-\alpha_1}$ must grow asymptotically at the same rate. Then from (B.19) and (B.20), we have

$$Y_{dt} = O(A_{ct}) \text{ and } Y_{ct} = O(A_{ct}), \quad (\text{B.25})$$

so that $g = \gamma\eta_c s_c$, where s_c is the asymptotic fraction of scientists working on clean research.

For $P_t^{\alpha_2} A_{ct}^{1-\alpha}$ and $A_{dt}^{1-\alpha_1}$ to grow at the same rate, it is then necessary (using (27)) that:

$$\frac{\alpha_2}{1 - \alpha_1} (\ln(1 + \rho) + \sigma \ln(1 + \gamma\eta_c s_c)) + \frac{1 - \alpha}{1 - \alpha_1} \ln(1 + \gamma\eta_c s_c) = \ln(1 + \gamma\eta_d (1 - s_c))$$

which in turn is impossible if $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$ (the above equation would then imply that $s_c < 0$, which cannot be).

This concludes Part 1, namely we have shown that if $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$ then innovation occurs in the clean sector only in the long run.

Part 2: We now show that if innovation does not switch to the clean sector in finite time then a disaster is bound to occur when $\ln(1 + \rho) < [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$. Indeed, suppose that innovation does not switch to the clean sector in finite time. Then, either innovation ends up occurring in the dirty sector only, or innovation keeps occurring in both sectors forever. In the former case, dirty input production must grow at rate g given by (B.24), which is strictly positive if $\ln(1 + \rho) < [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$. In the latter case, (B.25) implies that Y_{dt} will grow over time, again leading to a disaster.

Part 3: We now assume that innovation occurs in the clean sector only. Using (B.20) we get $g = \gamma\eta_c$ and using (B.19) we get:

$$Y_{dt} = O(P_t^{-\varepsilon\alpha_2} A_{ct}^{\alpha+\varphi}).$$

Thus overall Y_{dt} grows at rate g_{Y_d} satisfying:

$$\ln(1 + g_{Y_d}) = (1 - \varepsilon(1 - \alpha)) \ln(1 + \gamma\eta_c) - \varepsilon\alpha_2 (\ln(1 + \rho) + \sigma \ln(1 + \gamma\eta_c)).$$

Now, if $g_{Y_d} > 0$, then a disaster cannot be avoided. However, when $g_{Y_d} < 0$, and provided that the initial environmental quality is sufficiently large, a disaster is avoided.

Conclusion: Part 1 shows that when $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$, innovation must eventually occur in the clean sector only. Part 3 then shows that in that case and provided that $(1 - \varepsilon(1 - \alpha)) \ln(1 + \gamma\eta_c) - \varepsilon\alpha_2 (\ln(1 + \rho) + \sigma \ln(1 + \gamma\eta_c)) < 0$, a disaster is indeed avoided for sufficiently large initial environmental quality. This last condition in turn is met whenever $\varepsilon > \frac{1}{2 - \alpha - \alpha_1}$ if $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma \max(\eta_d, \eta_c))$. This proves the first claim of Proposition (9). Then Part 2 establishes that when innovation does not occur in the clean sector only in the long run, then a disaster is bound to occur if $\ln(1 + \rho) \neq [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$ (when $\ln(1 + \rho) > [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$, we know that innovation has to occur in the clean sector asymptotically). Finally, Part 3 shows that even when innovation ends up occurring in the clean sector only, yet a disaster occurs if $(1 - \varepsilon(1 - \alpha)) \ln(1 + \gamma\eta_c) - \varepsilon\alpha_2 (\ln(1 + \rho) + \sigma \ln(1 + \gamma\eta_c)) > 0$ or equivalently if $\ln(1 + \rho) < (1/\varepsilon - (1 - \alpha) - \alpha_2\sigma) \ln(1 + \gamma\eta_c) / \alpha_2$. Thus no matter where innovation occurs asymptotically, if $\ln(1 + \rho) < (1/\varepsilon - (1 - \alpha) - \alpha_2\sigma) \ln(1 + \gamma\eta_c) / \alpha_2$ and $\ln(1 + \rho) \neq [(1 - \alpha_1) / \alpha_2] \ln(1 + \gamma\eta_d)$, a disaster is bound to occur. This proves the second claim of Proposition (9).

Perfect competition in the absence of innovation

Here we show how our results are slightly modified if, instead of having monopoly rights

randomly attributed to “entrepreneurs” when innovation does not occur, machines are produced competitively. There are two types of machines. Those where innovation occurred at the beginning of the period are produced monopolistically with demand function $x_{jit} = x_{jit}^m = \left(\frac{\alpha^2 p_{jt}}{\psi}\right)^{\frac{1}{1-\alpha}} L_{jt} A_{jit}$. Those for which innovation failed are produced competitively. In this case, machines are priced at marginal cost ψ , which leads to a demand for competitively produced machines equal to $x_{jit} = x_{jit}^c = \left(\frac{\alpha p_{jt}}{\psi}\right)^{\frac{1}{1-\alpha}} L_{jt} A_{jit}$. The number of machines produced under monopoly is simply given by $\eta_j s_{jt}$ (the number of successful innovation).

Hence the equilibrium production of input j is given by

$$\begin{aligned} Y_{jt} &= L_{jt}^{1-\alpha} \int_0^1 A_{jit}^{1-\alpha} (\eta_j s_{jt} (x_{jit}^m)^\alpha + (1 - \eta_j s_{jt}) (x_{jit}^c)^\alpha) di \\ &= \left(\frac{\alpha p_{jt}}{\psi}\right)^{\frac{\alpha}{1-\alpha}} (\eta_j s_{jt} (\alpha^{\frac{\alpha}{1-\alpha}} - 1) + 1) A_{jt} L_{jt} \\ &= \left(\frac{\alpha p_{jt}}{\psi}\right)^{\frac{\alpha}{1-\alpha}} \widetilde{A}_{jt} L_{jt} \end{aligned}$$

where s_j is the number of scientists employed in clean industries and $\widetilde{A}_{jt} = (\eta_j s_{jt} (\alpha^{\frac{\alpha}{1-\alpha}} - 1) + 1) A_{jt}$ is the average corrected productivity level in sector j (taking into account that some machines are produced by monopolists and others are not).

The equilibrium price ratio is now equal to:

$$\frac{p_{ct}}{p_{dt}} = \left(\frac{\widetilde{A}_{ct}}{\widetilde{A}_{dt}}\right)^{-(1-\alpha)},$$

and the equilibrium labor ratio becomes:

$$\frac{L_{ct}}{L_{dt}} = \left(\frac{\widetilde{A}_{ct}}{\widetilde{A}_{dt}}\right)^{-\varphi}.$$

The ratio of expected profits from innovation in clean versus dirty sector now becomes

$$\begin{aligned} \frac{\Pi_{ct}}{\Pi_{dt}} &= \frac{\eta_c}{\eta_d} \left(\frac{p_{ct}}{p_{dt}}\right)^{\frac{1}{1-\alpha}} \frac{L_{ct} A_{ct-1}}{L_{dt} A_{dt-1}} \\ &= \frac{\eta_c}{\eta_d} \left(\frac{(\eta_c s_{ct} (\alpha^{\frac{\alpha}{1-\alpha}} - 1) + 1) (1 + \gamma \eta_c s_{ct})}{(\eta_d s_{dt} (\alpha^{\frac{\alpha}{1-\alpha}} - 1) + 1) (1 + \gamma \eta_d s_{dt})}\right)^{-\varphi-1} \left(\frac{A_{ct-1}}{A_{dt-1}}\right)^{-\varphi} \end{aligned}$$

This yields the modified lemma:

Lemma 3 *In the decentralized equilibrium, innovation at time t can occur in the clean sector only when $\eta_c A_{ct-1}^{-\varphi} > \eta_d \left((1 + \gamma \eta_c) \left((\eta_c (\alpha^{\frac{\alpha}{1-\alpha}} - 1) + 1) \right) \right)^{\varphi+1} A_{dt-1}^{-\varphi}$, in the dirty sector only*

when $\eta_c \left((1 + \gamma\eta_d) \left(\left(\eta_d \left(\alpha^{\frac{\alpha}{1-\alpha}} - 1 \right) + 1 \right) \right) \right)^{\varphi+1} A_{ct-1}^{-\varphi} < \eta_d A_{dt-1}^{-\varphi}$ and can occur in both when $\eta_c \left(\left(\eta_d s_{dt} \left(\alpha^{\frac{\alpha}{1-\alpha}} - 1 \right) + 1 \right) (1 + \gamma\eta_d s_{dt}) \right)^{\varphi+1} A_{ct-1}^{-\varphi} = \eta_d \left(\left(\eta_c s_{ct} \left(\alpha^{\frac{\alpha}{1-\alpha}} - 1 \right) + 1 \right) (1 + \gamma\eta_c s_{ct}) \right)^{\varphi+1} A_{dt-1}^{-\varphi}$.

This modified lemma can then be used to prove the analogs of Propositions 1, 2 and 3 in the text. The results with exhaustible resource can similarly be generalized to this case.

Calibration for the exhaustible resource case

We perform a similar calibration exercise as in the Section 6. As in the text, a time period corresponds to 5 years, $\gamma = 1$ and $\alpha = 1/3$, and Y_{c0} and Y_{d0} are still identified with the world production of energy from non-fossil and from fossil fuel origins respectively between 2002 and 2006. The definitions of S , ξ , and δ , and the utility function $u(C, S)$ are also the same as in the baseline calibration. To map our model, which has one exhaustible resource, to data, we focus on oil use and we compute the share of world energy produced from crude oil in the total amount of energy produced from fossil fuels from 2002 to 2006 (still according to the EIA). We then convert units of crude oil production and stock into units of total fossil production and stock by dividing the former by the share of world energy produced with oil relative to the world energy produced by any fossil fuel. We approximate the price for the exhaustible resource in our model by the refiner acquisition cost of imported crude oil in the United States (measured in 2000 chained dollars and again taken from the EIA). We extract the trend from the price series between 1970 and 2007 using the HP filter with the smoothing parameter of 100. We then restrict attention to the period 1997-2007 (during which the filtered real price of oil increases) and parameterize this price trend as a quadratic function of the estimated reserves of fossil resource. The estimated price of the fossil resource in 2002, combined with the consumption of fossil resource between 2002 and 2006 together with the value of world GDP from 2002 to 2006 from the World Bank, and the initial values of Y_{c0} and Y_{d0} , then allow us to compute α_2 , A_{c0} and A_{d0} and the cost function $c(Q)$ as the price of the exhaustible resource in units of the final good. This procedure gives $\alpha_2 = 0.0448$. Finally η_c is still taken to be 2% per year, but η_d needs to be rescaled. Indeed, if innovation occurs in the dirty sector only, output in the long-run—abstracting from the exhaustion of the natural resource—will be proportional to $A_d^{\frac{1-\alpha_1}{1-\alpha}}$ instead of A_d , so we compute η_d such that innovation in the dirty sector still corresponds to the same long-run annual growth rate of 2% after making this correction.

We now show how the optimal policy with exhaustible resource compares with that in the baseline case for the four configurations of (ε, ρ) (ε taking the high value of 10 and the low value of 3, ρ taking the high value of 0.015 and the low value of 0.001).

Optimal policy for $\varepsilon = 10$ or 3 and $\rho = 0.015$ or 0.001 , in exhaustible and non exhaustible cases

As illustrated by Figure 2B, the switch towards clean innovation again occurs immediately for $(\varepsilon = 10, \rho = 0.001)$, $(\varepsilon = 10, \rho = 0.015)$ and $(\varepsilon = 10, \rho = 0.001)$. The switch to clean innovation occurs slightly later in the exhaustible resource case when $(\varepsilon = 3, \rho = 0.015)$. The reason for this slight delay is that even though the growth prospects in the dirty sector are hampered by the depletion of the resource (this pushes towards an earlier switch to clean innovation), we also have that less dirty input is being produced in the exhaustible resource-3 case, which in turn can accommodate a later switch to clean innovation. Which effect dominates in practice depends on the parameters.

Moreover, with the exhaustible resource, the clean research subsidy does not need to be as high as in the baseline case to induce the switch because of the costs of the resource (see Figure

2A). For the same reason, the carbon tax does not need to be as high either (Figure 2C) and the switch to clean production occurs earlier than in the baseline, except when ($\varepsilon = 3, \rho = 0.015$), whereby the later switch in innovation mitigates the effect of the increase in the extraction cost so that the switch to clean production occurs around the same time (Figure 2D). The figure also shows that when ε is smaller, the resource tax needs to be higher, as more of the resource ends up being extracted at any point in time, and that temperature increases less over time with the exhaustible resource.
