Peroxisome proliferator-activated receptor-γ coactivator-1α in muscle links metabolism to inflammation

Handschin, C
Peroxisome proliferator-activated receptor-γ coactivator-1α in muscle links metabolism to inflammation

Abstract

1. In higher eukaryotes, metabolism and immunity are tightly coupled. However, whereas evolutionary, a compromised immune response due to undernourishment has been the predominant problem, the inflammatory response to obesity and other life style-associated diseases gained in relevance in Western societies in the last hundred years. 2. Traditionally, fat tissue has been considered as the major source of proinflammatory secreted factors in these pathologies. In recent years however, the contribution of other tissues to a disease-causing chronic inflammation has been increasingly appreciated. 3. The peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α) is one of the key regulatory factors in the active skeletal muscle. Aberrant expression of PGC-1α in inactive muscle fibers could link a sedentary life style, persistent systemic inflammation and the higher risk for many chronic diseases. Modulation of PGC-1α activity in skeletal muscle might accordingly have a broad therapeutic effect. Here, recent advances in the understanding of the role of muscle PGC-1α in health and disease are reviewed.
PGC-1α in muscle links metabolism to inflammation

Short title: Metabolism and inflammation in muscle

Abbreviations: AMPK, AMP-dependent protein kinase; IL-6, interleukin-6; MAPK, mitogen-activated protein kinase; NMJ, neuromuscular junction; NO, nitric oxide; PGC-1α, peroxisome proliferator-activated receptor γ coactivator 1α; SIRT, silencing information regulator; TNFα, tumor necrosis factor α;
Summary

1. In higher eukaryotes, metabolism and immunity are tightly coupled. However, whereas evolutionary, a compromised immune response due to undernourishment has been the predominant problem, the inflammatory response to obesity and other lifestyle-associated diseases gained in relevance in Western societies in the last hundred years.

2. Traditionally, fat tissue has been considered as the major source of pro-inflammatory secreted factors in these pathologies. In recent years however, the contribution of other tissues to a disease-causing chronic inflammation has been increasingly appreciated.

3. The peroxisome proliferator-activated receptor \(\gamma\) coactivator 1\(\alpha\) (PGC-1\(\alpha\)) is one of the key regulatory factors in the active skeletal muscle. Aberrant expression of PGC-1\(\alpha\) in inactive muscle fibers could link a sedentary lifestyle, persistent systemic inflammation and the higher risk for many chronic diseases. Modulation of PGC-1\(\alpha\) activity in skeletal muscle might accordingly have a broad therapeutic effect. Here, recent advances in the understanding of the role of muscle PGC-1\(\alpha\) in health and disease are reviewed.

Key words: Skeletal muscle, metabolism, inflammation, transcriptional regulation, PGC-1\(\alpha\)
**Introduction**

Multicellular organisms depend on the ability to store energy for times of famine and to fight infections\(^1\)-\(^2\). The immune response is very energy demanding and therefore, inflammatory processes strongly inhibit anabolic processes such as those controlled by insulin signaling. For example, fever boosts energy consumption by 7-13% per 1°C increase in body temperature, sepsis even by 30-60%\(^3\). On the other hand, an undernourished state is immunosuppressive, as observed malnourished or starving individuals with an increased susceptibility for infectious diseases. Accordingly, the molecular systems regulating metabolic processes and immune response have co-evolved and mutually regulate each other\(^4\). In lower organisms like the common fruit fly *Drosophila melanogaster*, metabolic and immune processes are even associated with one organ, the fat body, whereas in higher organisms, a deeper specialization of tissues occurred. Nevertheless, even in humans, metabolic organs are often closely linked with immune cells or have intrinsic immunomodulatory functions. For example, in the liver, hepatocytes are located adjacent to Kupffer cells, and macrophages are in close contact to adipocytes in fat\(^1\)-\(^2\)-\(^4\).

In the past 100 years, physical activity and food intake patterns have changed drastically in Western countries. Concomitant with this shift in energy metabolism, the incidence rates for obesity, type 2 diabetes, cardiovascular disease, hypertension and other lifestyle-associated pathologies have reached
epidemic proportions\textsuperscript{5, 6}. Thus, in contrast to the previous 250'000 years when \textit{Homo sapiens} mainly struggled with a lack of food, we now pay the price for an abundance of energy-rich food and the decreased importance of physical activity in daily life. Like malnutrition, overnutrition is linked to pathological changes in immune function, however in the diametrically opposite way. In contrast to the immunosuppression in undernourished individuals, the dysbalance between energy intake and dissipation triggered by overnutrition leads to a persistent, low-grade inflammatory state and an increased susceptibility to chronic diseases\textsuperscript{2, 4}. Importantly, this chronic inflammation is different from the classic immune response to an infectious agent and thus has been referred to as meta- or para-inflammation\textsuperscript{2, 4}. However, the same organs at the intersection of metabolism and immune function are involved in precipitating all of these different inflammatory responses\textsuperscript{7}.

**Adipose tissue is a major driver of inflammation in obesity**

Excess energy is mostly stored in adipose tissue where adipocytes become enlarged, ultimately resulting in obesity. In addition to energy storage, fat is an important endocrine organ and accordingly secretes a number of hormones that regulate systemic energy homeostasis and appetite\textsuperscript{8-10}. In an obese individual, adipocytes are also a major source of pro-inflammatory cytokines and other detrimental factors\textsuperscript{10, 11}. Gökhan Hotamisligil, Bruce M. Spiegelman and colleagues described the production and secretion of the tumor necrosis factor $\alpha$
(TNFα) by fat tissue in 1993 and thereby provided the first link between obesity, inflammation and insulin resistance12. In the meantime, numerous other adipose-derived pro-inflammatory proteins, members of the “adipokine” family, have been identified11, 13. Once released, many of these hormones promote insulin resistance in other peripheral tissues. Thus, an inflammatory response from adipose tissue and to a lesser extent from the liver triggers early, disease-causing events in obesity.

**Skeletal muscle as an endocrine organ**

Although an increased production of TNFα in skeletal muscle of obese patients has been reported in 199614, skeletal muscle as a significant contributor to chronic inflammation in metabolic diseases has been neglected for years. This is surprising since skeletal muscle makes up around 40% of body weight and is the largest storage site for glucose in the form of glycogen. Moreover, in a healthy organism, muscle tissue is very sensitive to insulin and the developing insulin resistance of this tissue contributes significantly to the etiology of type 2 diabetes15, 16. Finally, a sedentary life-style is a strong and independent risk factor for many chronic diseases, including those that are associated with persistent, systemic inflammation17. For example, lack of adequate physical activity is linked to type 2 diabetes, obesity, cardiovascular diseases, certain cancers, neurodegeneration, musculoskeletal disorders and other pathologies, thereby increasing morbidity and mortality and reducing the quality of life as well
as overall life expectancy\textsuperscript{17}. In contrast, exercise, even in the absence of significant weight loss, is an excellent preventative and therapeutic intervention for many chronic disorders\textsuperscript{18}. For example, changes in life-style that consist of diet and exercise rival or even exceed currently prescribed drugs in terms of therapeutic efficacy against type 2 diabetes\textsuperscript{19}.

In recent years, factors produced and secreted by the contracting muscle fibers have been found and termed “myokines”, analogous to the adipokines that are released from fat\textsuperscript{20}. Interestingly, many myokines have a complex expression pattern and exert beneficial and detrimental effects, respectively, depending on the cellular context\textsuperscript{20-22}. For example, short-lived pulses of interleukin-6 (IL-6), IL-8 and IL-15 are elicited by moderate exercise bouts and could mediate some of the systemic effects of physical activity (Fig. 1)\textsuperscript{23, 24}. In contrast, persistent elevation of IL-6 is strongly associated with obesity and type 2 diabetes\textsuperscript{4}. Thus, depending on the secretion pattern and the cellular context, IL-6 might mediate pro- or anti-inflammatory effects\textsuperscript{22}. Very high-intensity exercise paradigms are accompanied with the elevation of a specific set of cytokines that includes IL-6 and the unequivocally pro-inflammatory TNF\textsubscript{α}\textsuperscript{20, 25}. In that context, these myokines most likely contribute to the immunocompromised and inflammatory state that is observed after extreme physical activity\textsuperscript{25}.

**PGC-1α regulates muscle fiber plasticity**
Exercise triggers major phenotypic adaptations in skeletal muscle. This biological program is predominantly regulated by changes in gene transcription\(^26\). Importantly, molecular changes in myofibers differ between the acute adaptations to individual bouts of exercise and those observed in a chronically trained muscle. In both cases however, similar signaling pathways are responsible for initiating the adaptations. Motor neuron activation of muscle fibers results in an elevation of intracellular calcium levels\(^27-29\). Increased energy metabolism and hence ATP consumption shifts the ATP to AMP ratio and thereby activates the AMP-dependent protein kinase (AMPK)\(^30, 31\). At the same time, an altered NAD+ to NADH ratio alters the activity of the silencing information regulator 2-ortholog SIRT1\(^32-34\). The cellular stress associated with fiber contraction leads to an increased activity of the p38 mitogen-activated protein kinase (p38 MAPK) and the production of nitric oxide (NO)\(^35, 36\). Hormonal changes elicited by the fight-or-flight reaction to physical activity include elevated levels of \(\beta\)-adrenergic agonists, some of which bind to \(\beta_2\)-adrenoreceptors on the surface of muscle fibers\(^26, 37\).

Finally, the exercise-induced synaptic remodeling of the neuromuscular junction (NMJ) are initiated and maintained by motor neuron-released paracrine factors that act on muscle\(^38-40\). Importantly, all of these signaling pathways converge on the peroxisome proliferator-activated receptor \(\gamma\) coactivator 1\(\alpha\) (PGC-1\(\alpha\)) resulting in either a transcriptional induction, alteration of protein activity, or both (Fig. 2)\(^41, 42\). In turn, by binding to a diverse set of transcription factors, PGC-1\(\alpha\) regulates many, if not all of the adaptations of the muscle fiber to endurance exercise\(^41, 42\). First and foremost, PGC-1\(\alpha\) increases mitochondrial biogenesis.
and function. Accordingly, fatty acid β-oxidation, oxidative phosphorylation and ATP production are augmented. Then, the set of myofibrillar genes prototypical for the slow twitch, high endurance type I and IIa muscle fibers is induced by PGC-1α. Furthermore, the expression of the ubiquitine ligases that promote protein degradation and fiber atrophy in an inactive muscle is reduced. Finally, the transcriptional rate of genes encoding postsynaptic NMJ proteins is altered in synaptic nuclei. Accordingly, ectopic expression of PGC-1α in skeletal muscle is sufficient to promote a fiber-type shift towards a higher proportion of oxidative muscle fibers and thereby evoke a trained phenotype in the mouse model. By inducing the biological program for exercise, elevation of PGC-1α even prevents disuse-induced fiber atrophy, blunts the detrimental side-effects of statin drugs in muscle, ameliorates Duchenne muscular dystrophy and a form of a mitochondrial myopathy in the respective animal models.

**Pathological consequences of PGC-1α dysregulation in muscle**

In humans, a tight correlation between the relative levels of physical activity and PGC-1α has been observed (e.g., ref 51). PGC-1α expression is transiently elevated after each bout of endurance exercise, similar to the expression pattern described for IL-6. In a chronically trained muscle, basal levels of PGC-1α are higher than those observed in an untrained individual, yet a superimposed pulsative regulation of PGC-1α expression following each exercise bout is
maintained. In contrast, aberrantly low PGC-1α levels are found in the muscle of sedentary individuals and type 2 diabetic patients, at least in some populations. It is unknown how much this dysregulation contributes to the etiology and pathology of this disease. However, a significant contribution of PGC-1α on glucose homeostasis is implied by the results from muscle-specific knockout mouse models. Mirroring the data from PGC-1α muscle transgenic mice, PGC-1α muscle-specific knockout animals exhibit a higher number of glycolytic type IIx and IIb fibers concomitant with a reduction in mitochondrial gene expression and oxidative capacity. As a consequence, these mice are hypoactive and restricted in their ability to exercise. Moreover, whole body glucose and insulin homeostases are abnormally regulated. These findings confirm the important role for PGC-1α in metabolic and myofibrillar plasticity of muscle fibers. Surprisingly though, PGC-1α muscle-specific knockout animals reveal signs of muscle damage as revealed by an increase in plasma creatine kinase levels and the number of perforated fibers in histological stainings. Whereas this fiber damage is limited in sedentary animals, the myopathy is exacerbated by physical activity. Thus, physiological levels of PGC-1α seem essential for normal muscle fiber integrity.

Increased inflammation could link PGC-1α to muscle fiber damage

It is unclear how fiber damage is triggered in muscle-specific PGC-1α knockout animals. Similarly, the molecular mechanisms that underlie the therapeutic
effects of PGC-1α in different muscle diseases are unknown, although several candidate mechanisms have been suggested. Intriguingly, pro-inflammatory markers are elevated in mice with an ablated PGC-1α gene in muscle. In addition to the local inflammatory reaction in skeletal muscle, PGC-1α muscle-specific knockout animals exhibit higher levels of circulating TNFα and IL-6. Inflammation contributes to fiber damage and muscle wasting in a variety of different muscle diseases. Whether the inflammation in PGC-1α muscle-specific knockout mice is cause or consequence of the fiber damage has not been elucidated. For example, PGC-1α might directly modulate inflammatory gene expression, e.g., by altering reactive oxygen species in muscle, or the inflammation could be secondary to fiber damage and the subsequent removal of the debris. In any case however, the elevation of circulating pro-inflammatory factors and hence the systemic inflammatory state seems sufficient to link dysregulated muscle function to pathologies in other organs such as the deficient insulin secretion from pancreatic β cells in these animals.

Conclusions

Chronic systemic inflammation is associated with an increased risk for many diseases. In addition, exercise has health benefits on the whole body, not just skeletal muscle. Thus, intrinsic adaptations in muscle fibers and the consequent distal signaling, most likely by hormonal or neuronal pathways, must mediate the crosstalk between active muscles and other organs. Reduction of PGC-1α levels
and the subsequent systemic elevation of pro-inflammatory cytokines might be the elusive link between a sedentary life-style and the increased risk for chronic diseases (Fig. 1)\textsuperscript{57}. Accordingly, a pharmacological modulation of PGC-1α in muscle might have therapeutic benefits beyond that tissue. Unfortunately, despite various efforts, such compounds that robustly alter PGC-1α gene expression in skeletal muscle and not other tissues with potential detrimental side effects, and which can be safely and chronically used in patients remain elusive\textsuperscript{61, 62}. Thus, as long as the inherent limitations of targeting a coactivator protein have not been overcome, a healthy life-style remains the best remedy against chronic diseases.

Figure Legends

Fig. 1. Myokine production and the inflammatory state in skeletal muscle. Myokines secreted by an active muscle might contribute to the systemic beneficial effects of exercise. Reduced muscle activity is associated with impaired PGC-1α expression. A number of pro-inflammatory cytokines are elevated in individuals with inadequate physical activity. This persistent, low-grade inflammation could subsequently increase the risk for a number of chronic diseases. In contrast, extreme performances and the accompanying fiber damage result in a state of temporary immunosuppression.

Fig. 2. Regulation and function of PGC-1α in skeletal muscle fibers. All major signaling pathways that are activated in an active muscle fiber converge on the PGC-1α promoter, the protein or both. In turn, PGC-1α initiates the adaptations of muscle to physical activity by regulating metabolic, myofibrillar and neuromuscular junction-specific genes.
