Poly(ADP-ribose) polymerase 1 at the crossroad of metabolic stress and inflammation in aging

Abstract

Poly(ADP-ribose) polymerase 1 (PARP1) is a chromatin-associated nuclear protein, which functions as molecular stress sensor. Reactive oxygen species, responsible for the most plausible and currently acceptable global mechanism to explain the aging process, strongly activate the enzymatic activity of PARP1 and the formation of poly(ADP-ribose) (PAR) from NAD(+)*. Consumption of NAD(+) links PARP1 to energy metabolism and to a large number of NAD(+)‐dependent enzymes, such as the sirtuins. As transcriptional cofactor for NF‐kappaB‐dependent gene expression, PARP1 is also connected to the immune response, which is implicated in almost all age‐related or associated diseases. Accordingly, numerous experimental studies have demonstrated the beneficial effects of PARP inhibition for several age‐related diseases. This review summarizes recent findings on PARP1 and puts them in the context of metabolic stress and inflammation in aging.
Poly(ADP-ribose) polymerase 1 at the crossroad of metabolic stress and inflammation in aging

Abstract: Poly(ADP-ribose) polymerase 1 (PARP1) is a chromatin-associated nuclear protein, which functions as molecular stress sensor. Reactive oxygen species, responsible for the most plausible and currently acceptable global mechanism to explain the aging process, strongly activate the enzymatic activity of PARP1 and the formation of poly(ADP-ribose) (PAR) from NAD+. Consumption of NAD+ links PARP1 to energy metabolism and to a large number of NAD+-dependent enzymes, such as the sirtuins. As transcriptional cofactor for NF-κB-dependent gene expression, PARP1 is also connected to the immune response, which is implicated in almost all age-related or associated diseases. Accordingly, numerous experimental studies have demonstrated the beneficial effects of PARP inhibition for several age-related diseases. This review summarizes recent findings on PARP1 and puts them in the context of metabolic stress and inflammation in aging.

INTRODUCTION

Aging is a multi-factorial process defined as time-dependent general decline in physiological function, which is associated with a progressively increasing risk of frailty, morbidity and mortality [1, 2]. The effect of aging is mainly observed in modern human societies and in animals under laboratory conditions [3]. The dramatic increase in mean human life span and life expectancy, coupled to a significant reduction in early mortality caused by the reduced occurrence of infections during the past two centuries, has led to an enormous increase in the number of elderly people in modern societies [4, 5]. This demographic phenomenon has been paralleled by an epidemic of chronic diseases associated with advanced age, most of which have complex etiology and underlying pathogenic mechanisms [6]. Intensive efforts have been made over the last decades to identify single key players involved in age-related diseases. Poly(ADP-ribose) polymerase 1 (PARP1) is a chromatin-associated nuclear protein which functions as stress sensor and as such is involved in the cellular responses to a variety of age-related stress signals.

Poly(ADP-ribose) polymerase 1 as molecular stress sensor

PARP1 is an abundant nuclear chromatin-associated multifunctional enzyme found in most eukaryotes apart from yeast [7]. PARP1 has been initially thought to be the only existing enzyme with poly(ADP-ribose)ylation activity in mammalian cells. However, five additional Parp-like genes encoding “bona fide” PARP enzymes have been identified in recent years, indicating that PARP1 belongs to a family of “bona fide” PARP...
enzymes [8]. The basal enzymatic activity of PARP1 is very low, but is stimulated dramatically under conditions of cellular stress [9, 10]. Activation of PARP1 results in the synthesis of poly(ADP-ribose) (PAR) from nicotinamide adenine dinucleotide (NAD\(^\gamma\)) and in the release of nicotinamide as reaction by-product [7, 8]. Following PARP1 activation, intracellular PAR levels can rise 10–500-fold [11-13]. Despite intensive research on the cellular functions of PARP1, the molecular mechanism of PAR formation has not been comprehensively understood. Up to now, two different modes of PARP1 activation have been described, one dependent on DNA damage and one dependent on post-translational protein modifications (see below).

PAR is a heterogeneous linear or branched homopolymer of repeating ADP-ribose units linked by glycosidic ribose-ribose bonds [7, 9, 14]. Most free or protein-associated PAR molecules are rapidly degraded in vivo [15]. This rapid turnover strongly suggests that PAR levels are tightly regulated under physiological stress conditions and that degradation of the polymer starts immediately upon initiation of PAR synthesis. To date two enzymes, poly(ADP-ribose) glycohydrolase (PARG) and ADP-ribosyl protein lyase, have been described to be involved in PAR catabolism [16, 17]. While PARG possesses both exo- and endoglycosidic activities, the lyase has been described to cleave the bond between proteins and mono(ADP-ribose). The attachment of negatively charged PAR onto proteins is transient but can be very extensive in vivo, as polymer chains can reach more than 400 units on protein acceptors [7]. PAR formation has been implicated in a variety of cellular processes, such as maintenance of genomic stability, transcriptional regulation, energy metabolism and cell death [7]. The physiological consequences of this post-translational modification on the molecular level, however, are not yet completely understood. It has been proposed that PAR may have a dual role in modulating cell survival and cell death [9, 18, 19]. Low to moderate levels of PAR may be beneficial for important cellular functions, whereas extensive PAR formation can be detrimental and lead to various forms of cell death. More than a decade ago, PARP1 activity was linked to the aging process, as poly(ADP-ribosyl)ation capacity was shown to correlate with species-specific longevity [20, 21].

Most proteins associated with PAR are nuclear DNA-binding proteins, including PARP family members and histones [7, 22, 23]. PARP1 is the main acceptor for poly(ADP-ribosyl)ation in vivo and auto-modification of PARP1 abolishes its affinity for NAD\(^\gamma\) and DNA [24, 25]. A similar effect has been postulated for histones/nucleosomes. PAR polymers could function to alter chromatin conformation through covalent or non-covalent interactions with histone tails and via displacement of histones from DNA, thus regulating the accessibility of the genetic material. It was suggested that PAR might either directly participate in chromatin remodelling processes or indirectly coordinate them through recruitment and regulation of specific chromatin remodelling proteins [7, 22]. Moreover, PAR is recognized and bound by macrodomain containing histone variants [26].

Over 20 years ago, Nathan Berger was the first to suggest that cellular stress (e.g. oxidative damage) causes over-activation of PARP1 and subsequent NAD\(^\gamma\) depletion [27, 28]. In an attempt to restore the NAD pools, NAD\(^\gamma\) is resynthesized with a consumption of 2-4 molecules of ATP per molecule of NAD\(^\gamma\). As a consequence, cellular ATP levels become depleted, leading to subsequent energy failure, which results in cellular dysfunction and eventually in necrotic cell death [27, 28]. Pharmacological inhibition of the enzymatic activity of PARP or the complete absence of PARP1 was shown to significantly improve cellular energetic status and cell viability after exposure to necrosis-inducing agents [29-31]. The contribution of poly(ADP-ribosyl)ation reactions to necrotic cell death seems to be dependent on the cell type and the cellular metabolic status [7, 32, 33].

Interestingly, genetic studies using Parp1 knockout mice provided preliminary evidence that energy depletion alone might not be sufficient to mediate poly(ADP-ribosyl)ation-dependent cell death [34]. A second model has been proposed to explain how PARP1 regulates cell death. This model suggests that over-activation of PARP1 induces translocation of apoptosis-inducing factor (AIF) from the mitochondria to the nucleus, causing DNA condensation and fragmentation, and subsequent cell death [35].

Together, PARP1 can be regarded as molecular stress sensor with many physiological cellular functions. Over-activation of PARP1 results in the generation of large amounts of PAR. Subsequently, cellular NAD\(^\gamma\) pools are depleted and AIF is released from the mitochondria to trigger cell death. Importantly, these PARP1-dependent cellular suicide mechanisms have been implicated in the pathomechanisms of neurodegenerative disorders, cardiovascular dysfunction and various other forms of inflammation [36].

**Activation of PARP1 by reactive oxygen species (ROS)**

A unified theory explaining the pathogenesis of diverse degenerative conditions in different organs (including
Alzheimer's, Parkinson's and other neurodegenerative disorders, rheumatoid arthritis, atherosclerosis and other cardiovascular diseases, diabetes) has been proposed to explain how the single physiological process of aging may lead to diverse pathological states [37]. This oxidative stress theory of aging (or free radical theory of aging), initially proposed by Harman in 1956, provides the most plausible and currently acceptable global mechanism to explain the aging process [38]. The theory postulates that aging is, in the absence of other risk factors (e.g. infections, smoking, hypercholesterolemia), the net consequence of free radical-induced damage and the inability to counterbalance these changes by anti-oxidative defenses. An increase in intracellular ROS levels through hydrogen peroxide treatment of cells or through the inhibition of ROS scavenging enzymes, such as superoxide dismutase (SOD1), causes premature senescence and can shorten cellular life span [39-45]. Mitochondria are the main producers of cellular ROS under normal conditions, as approximately 1-2% of the oxygen molecules consumed during respiration are converted into highly reactive superoxide anions [46]. Besides aerobic metabolism in mitochondria, β-oxidation in peroxisomes and certain enzymes can produce ROS. Intracellular ROS can damage cellular components through oxidation of macromolecules such as nucleic acids, proteins and lipids [47]. Moreover, an overproduction of ROS leads to rapid generation of peroxinitrite from nitric oxide and superoxide, causing an imbalance in nitric oxide signaling [48].

Since the oxidative stress theory was first proposed, a considerable body of evidence has been published corroborating the idea that increased production of ROS underlies cellular dysfunction in various organ systems of aged humans and laboratory animals [49]. Interestingly, the enzymatic activity of PARP1 can be strongly activated by treatment of cells with ROS such as hydrogen peroxide [8]. Earlier studies described that PARP1 binds to oxidative damage-induced strand breaks within the DNA via two zinc finger motifs and thereby becomes activated [9]. More recently, several studies suggested that PARP1 activity is also regulated in a DNA-independent manner. A proteomic investigation uncovered many ERK1/2-induced phosphorylation sites in PARP1, which are located within important functional domains, consistent with regulatory roles in vivo [50, 51]. Furthermore, DNA-independent PARP1 activation can be triggered by the direct interaction of PARP1 with phosphorylated ERK-2 without PARP1 being phosphorylated itself [52]. In addition, PARP1 can be activated by elevated levels of extracellular glucose, Ca\(^{2+}\), polyamines, ATP and the histones H1 and H3 has been reported [53]. Whether ROS-mediated activation of PARP1 is due to ROS-generated DNA damage or also based on other ROS-induced cellular (signaling) mechanisms awaits further investigations.

**PARP1 is linked to energy metabolism through NAD\(^{+}\)**

NAD\(^{+}\) biosynthesis has become of considerable interest due to the important signaling functions of pyridine nucleotides. In mammals, niacin (collectively designating nicotinamide and nicotinic acid) and the essential amino acid tryptophan are precursors of NAD\(^{+}\) biosynthesis [12, 54]. The formation of dinucleotides from ATP and the mononucleotide of niacin constitute the most critical step in NAD\(^{+}\) generation, which is catalyzed by NMN/NaMN adenyltransferases (NMNATs) [13, 55]. Since PARP1 uses NAD\(^{+}\) as substrate to synthesize PAR, PARP1 decisively depends on the amount of NAD\(^{+}\) available and may act as an energy sensor in the nucleus. Both constitutive and activated levels of PAR have been suggested to be strictly dependent on the concentration of NAD\(^{+}\) in cells [15, 56, 57]. Importantly, the nuclear concentration of NAD\(^{+}\) can be modulated by NMNAT-1 and a recent study revealed that NNMAT-1 is able to interact with and stimulate PARP1 [58]. It is thus tempting to speculate that PARP1 activation is supported by the localized action of NNMAT-1. Depending on the level of PARP1 activity, the cellular NAD\(^{+}\) concentration is concomitantly reduced. Therefore, PARP1 not only is a sensor of NAD\(^{+}\), but in turn also influences cellular energy levels.

Dietary restriction, also called caloric restriction, is defined as a life-long moderate (20-40%) reduction in caloric intake and has repeatedly been shown to extend the longevity of both invertebrates and vertebrates [59, 60]. Reducing the caloric intake starting even at an old age has also been shown to increase the life span of flies and mice and is sufficient to reverse gene expression changes associated with aging [61-63]. Furthermore, dietary restriction in rodents delays the onset and reduces the severity of many age-related diseases, such as cardiovascular disease, diabetes, osteoporosis, cataracts, neurodegenerative disease and cancers [60]. Although it was initially expected that dietary restriction would reduce overall cellular energy levels by slowing down glycolysis and the tricarboxylic acid (TCA) cycle [59], this assumption has been challenged, since dietary restriction was shown to cause an increase in NAD\(^{+}\)/NADH ratios in yeast cultures [64]. Whether this is also the case in mammalian cells remains to be determined. Along the same lines, the impact of dietary
NAD$^+$ is an essential cofactor regulating numerous cellular pathways and has recently been recognized as a substrate for a growing number of NAD$^+$-dependent enzymes [11, 13]. NAD$^+$-dependent post-translational protein modifications are catalyzed by several enzyme families, including PARPs and the sirtuin family of NAD$^+$-dependent class III histone deacetylases (SIRTs) [8, 65, 66]. SIRTs and the yeast homolog and founding member of the sirtuins, Sir2, are induced by dietary restriction and have been implicated in senescence and aging, although the exact mechanisms are not yet known [59, 67]. Intriguingly, ADP-ribosylation by PARP1 could modulate the NAD$^+$-dependent deacetylation of proteins by SIRTs via the NAD$^+$-nicotinamide connection. The decline of NAD$^+$ levels and the rise of nicotinamide upon PARP1 activation have immediate effects on other NAD$^+$-consuming enzymes [57, 68, 69]. SIRTs require NAD$^+$ as substrate and are inhibited by low levels of nicotinamide [70]. Consequently, under conditions of cellular stress and PARP1 activation, the activity of SIRTs is downregulated.

PARPs and sirtuins may not only compete for the same substrate, but might also regulate each other more directly. For instance, PARP1 and SIRT1 interact at the protein level and SIRT1 might be regulated by PARP1-dependent trans-ADP-ribosylation [7]. Another link between PAR generation and acetylation/deacetylation reactions comes from the very recent identification of three lysine residues in the auto-modification domain of PARP1 as acceptor sites for auto-ADP-ribosylation [71]. The same lysines were previously identified as targets for acetylation by p300 and PCAF [72]. Remarkably, simple addition of PCAF reduced poly(ADP-ribosylation) of PARP1 (own unpublished observation), suggesting that the interaction domain of PARP1 with PCAF is overlapping with the ADP-ribose acceptor sites. We recently also published that acetylation of lysine residues interferes with ADP-ribosylation [73]. This finding points at an interesting crosstalk between acetylation of and ADP-ribosylation by PARP family members. It will certainly be interesting to further investigate the crosstalk between PARP1-dependent ADP-ribosylation and acetylation/deacetylation reactions. NAD$^+$ levels can be expected to play an important role for the interplay between these two NAD$^+$-dependent post-translational protein modifications. Whether the balance between and the tight regulation of poly(ADP-ribosyl)ation and NAD$^+$-dependent deacetylation is altered during aging remains to be investigated. Furthermore, it will be important to identify additional NAD$^+$-dependent enzymes involved in the aging process.

Emerging pathological evidence indicates that major chronic age-related diseases, such as atherosclerosis, arthritis, dementia, osteoporosis and cardiovascular disease, are inflammation-related [74]. A link between NAD$^+$ metabolism and the regulation of an inflammatory response is suggested by the finding that nicotinamide phosphoribosyltransferase (NAMPT), one of the enzymes involved in NAD$^+$ biosynthesis from nicotinamide, increases cellular NAD$^+$ levels in response to stress [75]. The expression of NAMPT is upregulated in activated lymphocytes [76]. Furthermore, NAMPT protein and/or mRNA levels were also found to be upregulated upon stimulation of immune cells both in vivo and in vitro [77, 78], whereas a specific NAMPT inhibitor was found to inhibit cytokine production [79]. Notably, nicotinamide is known to inhibit the production of key inflammatory mediators [80-82], protects neurons against excitotoxicity [83, 84], and blocks replicative senescence of primary cells [85]. Moreover, a recent study suggested that intracellular NAD$^+$ levels regulate TNF-α protein synthesis in a SIRT6-dependent manner [86]. Both, SIRT1 and SIRT6 also regulate NF-κB signaling with effects on senescence and possibly aging [87, 88].

Together, accumulating evidence suggests that cellular NAD$^+$ biosynthesis and the NAD$^+$-consuming reactions poly(ADP-ribosylation) and SIRT-dependent deacetylation are tightly interrelated and have functions in inflammation and age-related diseases.

**PARP1 is linked to age-related inflammation as transcriptional cofactor of NF-κB**

A body of experimental and clinical evidence suggests that the immune system is implicated in almost all age-related or associated diseases [89, 90]. There is a well-established connection between oxidative stress and the inflammatory immune response [37]. A prominent mechanism by which age-induced ROS modulate inflammation is by inducing the redox-sensitive transcription factor nuclear factor kappa B (NF-κB). This induction of NF-κB leads to the generation of pro-inflammatory mediators and a state of chronic
inflammation [91, 92]. NF-κB plays an important role in inflammatory phenotypic changes in various pathophysiological conditions [49]. In fact, NF-κB has a fundamental role in mediating all the classical attributes of inflammation – rubor, calor, dolor and tumor – by regulating transcriptional programs in tissues containing epithelial and stromal cells, vascular endothelial cells and hematopoietic cells [93]. During the last decade, it has been clearly demonstrated that excessive activation or inappropriate regulation of immune and inflammation cascades causes tissue and cellular damage, which can lead to cellular dysfunction and death [14]. Furthermore, it was suggested that chronic, low-grade inflammation is a possible converging process linking normal aging and the pathogenesis of age-related diseases [94]. This hypothesis is in accordance with the finding that constitutive activation of NF-κB, accompanied by elevated levels of inflammatory markers, is a ubiquitous phenomenon observed in various cell types in the aging phenotype [95].

In most unstimulated cells, NF-κB is sequestered in the cytoplasm as an inactive transcription factor complex by its physical association with one of several inhibitors of NF-κB (IκB) [96-100]. The key regulatory event in NF-κB induction is the phosphorylation of IκB proteins by the IκB kinase (IKK) complex, which leads to IκB protein ubiquitylation and subsequent degradation [101, 102]. ROS have been reported to induce the activation of NIK/IKK and MAPK pathways that lead to the degradation of IκB and subsequent NF-κB-dependent gene expression [74, 103]. Conversely, induction of NF-κB itself results in the generation of ROS via the expression of inducible nitric oxide synthase (iNOS), thus activating a feedback loop that amplifies the process of damage and deterioration in target cells and organs [37].

Global screens for age-specific gene regulation have been performed from many tissues in mice and humans [3]. These analyses have recently provided evidence that the NF-κB binding domain is the genetic regulatory motif most strongly associated with the aging process and that NF-κB target genes show a strong increase in expression with age in human and mouse tissues as well as in stem cells [104-106]. Furthermore, NF-κB is implicated in age-dependent induction of cellular senescence in epithelial and hematopoietic progenitor cells [104, 107]. Blockade of NF-κB in the skin of aged mice can reverse the global gene expression program and tissue characteristics to that of younger animals [108]. Moreover, Donato et al. reported lately that in vascular endothelial cells of aged human donors nuclear NF-κB levels increase, IκBα levels decrease and that the expression of proinflammatory cytokines, such as interleukin 6 (IL-6), tumor necrosis factor-α (TNF-α) and monocyte chemoattractant protein 1 (MCP-1) is reduced [109]. NF-κB activity was also increased in aged rat vessels and kidneys, but reduced in rats under calorie restriction [110, 111].

Studies performed with Parp1 knockout mice have identified various detrimental functions of PARP1 in inflammatory and neurodegenerative disorders. Parp1 gene-disruption protected from tissue injury in various oxidative stress-related disease models ranging from stroke, (MPTP)-induced parkinsonism, myocardial infarction, streptozotocin-induced diabetes, lipopolysaccharide-induced septic shock, arthritis, to colitis and zymosan-induced multiple organ failure [7, 73, 112, 113]. There are striking similarities between the expression pattern of PARP1 and the detrimental transcriptional activity of NF-κB. In most tissues and cell types associated with high PARP1 expression, dysregulated NF-κB activity seems to contribute to cellular dysfunction and necrotic cell death during inflammatory disorders [14]. The strongest indication for a direct role of PARP1 in NF-κB-dependent transcription was the impaired expression of NF-κB-dependent pro-inflammatory mediators in Parp1 knockout mice [113]. Moreover, the upregulation of several inflammatory response genes after treatment with inflammatory stimuli was drastically reduced in Parp1 knockout mice [112, 114-116]. Our group provided first evidence that PARP1 is required for specific NF-κB-dependent gene activation and can act as transcriptional coactivator of NF-κB in vivo [117]. PARP1 is required and sufficient for specific transcriptional activation of NF-κB in response to pro-inflammatory stimuli and cellular stress. Furthermore, Tulin and Spradling found that Drosophila mutants lacking normal PARP levels display immune defects similar to mice lacking the NF-κB subunit p50 [118]. These results imply that the role of PARP1 in NF-κB-dependent gene expression during immune responses has been conserved during evolution. Together, several lines of evidence suggest a model in which PARP1 functions as a promoter-specific cofactor for NF-κB-dependent gene expression [7, 14].

**PARP as therapeutic target for age-associated diseases**

During the last two decades of intensive research, over 50 potential PARP inhibitors were developed [119]. The involvement of PARP1 in cell death (both apoptosis and necrosis) and the capacity of PARP1 to promote the transcription of pro-inflammatory genes are particularly
important for drug development. On the basis of structural information available for the catalytic domains of PARP1 and PARP2 co-crystallized with NAD⁺ or certain PARP inhibitors, it became clear that the majority of PARP inhibitors mimic the nicotinamide moiety of NAD⁺ and bind to the donor site within the catalytic domain [120-122]. Although the physiological functions of PARPs and poly(ADP-ribosyl)ation is still under debate, numerous experimental studies during the last years have clearly demonstrated the beneficial effects of PARP inhibition from cell culture systems to pre-clinical animal models of acute and chronic inflammation [36, 119]. For instance, Vaziri and colleagues observed an extension of cellular life span when PARP activity was inhibited [123]. In animal studies, PARP inhibition and/or PARP1 deficiency is effective in different age-related diseases [119]. The PARP inhibitor 5-AIQ has been demonstrated to attenuate the expression of P-selectin and intracellular adhesion molecule-1 (ICAM-1) as well as the recruitment of neutrophils and leukocytes into the injured lung [124, 125]. Thus, application of inhibitors reduces the degree of acute inflammation and tissue damage associated with experimental lung injury. As ROS released from the recruited leukocytes cause an upregulation of adhesion molecules, treatment with PARP inhibitors contributes to the termination of this vicious cycle and inhibits the inflammatory process. Similar to the effects of pharmacological inhibitors, Parp1 knockout mice were found to be resistant against zymosan-induced inflammation and multiple organ failure when compared with the response of wild-type animals [126].

In murine models of arthritis, inhibition of PARP with nicotinamide delayed the onset of the disease and reduced the progress of established collagen-induced arthritis [127]. 5-iodo-6-amino-1,2-benzopyrone and PJ34, two novel PARP inhibitors, were beneficial in a mouse model of collagen-induced arthritis by reducing both the incidence of arthritis and the severity of the disease [128, 129]. Similarly, GPI 6150 was found to be highly effective in a rodent model of adjuvant-induced arthritis [130].

PARP activation also has a pathogenic role in hypertension, atherosclerosis and diabetic cardiovascular complications [119, 131]. In these diseases, the function of the vascular endothelium is impaired, resulting in a reduced ability of the endothelial cells to produce nitric oxide and other cytoprotective mediators. This then sets the stage for many manifestations of cardiovascular disease. The oxidant-mediated endothelial cell injury is dependent on PARP1 and can be attenuated by pharmacological inhibitors or genetic PARP1 deficiency [115, 132]. Furthermore, PARP inhibition improves aging-associated cardiac and endothelial dysfunction [133].

In general, the severity of many inflammatory diseases is suppressed by PARP inhibitors and the production of multiple pro-inflammatory mediators is downregulated [48]. The inhibition of PARP also reduces the formation of nitrotyrosine in inflamed tissues, an indicator of reactive nitrogen species. This finding was, at first, unexpected because PARP activation is perceived to occur downstream of the generation of oxidants and free radicals in various diseases. The mechanism is probably related to the fact that PARP inhibition reduces the infiltration of neutrophils into inflammatory sites [126]. This in turn reduces oxygen- and nitrogen-centered free-radical production. The basis for the regulation of neutrophil infiltration by PARP might be related to the reduced expression of adhesion molecules [134, 135] and/or the preservation of endothelial integrity [115, 132]. Alternatively, the reduction of nitrotyrosine could be explained by the finding that PARP1 is required for the expression of iNOS, the main producer of nitric oxide in inflamed tissues [116]. In summary, multiple studies suggest that a tight regulation of PARP activity is required to prevent a variety of age-related pathological conditions.

Role of PARP1’s enzymatic activity in NF-κB-dependent gene expression

There is no consensus in the literature as to whether the modulation of NF-κB-mediated transcription by PARP1 is dependent on poly(ADP-ribosyl)ation or, alternatively, merely on the physical presence of PARP1 [14]. Genetic approaches provide strong evidence that poly(ADP-ribosyl)ation is not affecting the DNA binding activity of NF-κB and is not required for NF-κB-dependent gene expression [14, 136]. Neither the enzymatic activity of PARP1 nor its binding to DNA was required for full activation of NF-κB in response to various stimuli in vivo when tested on transiently transfected reporter plasmids [137, 138]. Consistently, the enzymatic activity of PARP1 was not required for full transcriptional activation of NF-κB in the presence of the histone acetyltransferase p300 [72]. At first glance this seems not to be compatible with reports describing that PARP inhibitors abolish mRNA expression of iNOS, IL-6 and TNF-α in cultured cells [139] or that PARP inhibitors reduce the expression of inflammatory mediators in mice [124, 126, 140]. However, this discrepancy might be explained in three ways: First, it should be noted that the currently available PARP inhibitors do not discriminate well between PARP1 and other PARP family members or
even other NAD⁺-metabolizing enzymes, which are described to also play a role in inflammatory response pathways [139, 141]. In Parp1 knockout mice, PAR formation is indeed drastically reduced only in brain, pancreas, liver, small intestine, colon, and testis, whereas still moderate levels of residual poly(ADP-ribose) formation can be observed in the stomach, bladder, thymus, heart, lung, kidney and spleen [7]. This residual activity can most likely be attributed to PARP2, which has the greatest similarity to PARP1 among all PARP family members [8]. Interestingly, PARP2 is involved in T lymphocyte development and survival [142] and has been implicated in inflammatory immune responses [143, 144]. A putative role of PARP2 in aging awaits further investigations. Second, based on recent reports, one cannot exclude the possibility that PARP-inhibitors might even affect non-NAD⁺-consuming targets such as AKT/PKB or MMPs [145]. Third, the enzymatic activity of PARP1 might be required for the transcriptional activity of transcription factors involved in inflammatory processes other than NF-κB. Several groups have shown that co-operative activities between transcription factors such as AP-1, STAT-1 or IRF-1 in the enhanceosomes of NF-κB dependent genes are required for full synergistic activation of target genes [146, 147]. Considering these constraints of all currently available PARP inhibitors, the specific contribution of PARP1 enzymatic activity for age-related diseases, in which PARP inhibition has beneficial effects, needs to be evaluated very carefully.

**Figure 1. PARP1 at the crossroad of metabolic stress and inflammation in aging.** PARP1 is activated by cellular stress, e.g. by oxidative damage due to increased levels of reactive oxygen species (ROS). As NAD⁺-dependent enzyme, PARP1 senses energy levels and crosstalks with other NAD⁺-consuming enzymes. Over-activation of PARP1 leads to energy depletion and cell death. On the other hand, PARP1 functions as cofactor for NF-κB-dependent transcription and is therefore implicated in many inflammatory processes. Both, PARP1-mediated metabolic stress and PARP1-regulated inflammation can lead to tissue degeneration underlying many age-related pathologies. See text for further details.
CONCLUSIONS

Several publications in the past years indicate that the nuclear protein PARP1 represents a molecular link between energy metabolism and inflammation (Figure). As NAD+-consuming enzyme, PARP1 acts as nutrient or energy sensor, crosstalks with other NAD+-consuming enzymes (such as sirtuins) and modulates (as regulator of NF-κB-dependent transcription of cytokines) inflammatory responses. Thus, PARP1 seems to be an ideal candidate to integrate metabolic and inflammatory signals, which arise during the process of aging. As central integrator, PARP1 may mediate cellular stress response pathways and thereby participate in a multitude of age-related pathologies. PARP inhibition has proven beneficial in many cell culture and animal model systems of acute and chronic inflammation and age-related diseases. Clearly, additional research will further improve our understanding of the functions of PARP1 and their implications in age-related diseases associated with metabolic stress and inflammation.

ACKNOWLEDGEMENTS

The authors acknowledge the contributions by researchers whose work could not be cited in this review due to space limitations. We thank Paul O. Hassa and Ingrid Kassner (both Institute of Veterinary Biochemistry and Molecular Biology, University of Zurich, Zurich, Switzerland) for critical reading of the manuscript and helpful discussions. Our own research on PARP1 is supported by SNF grants 31-109315.05 and 31-122421.08.

CONFLICT OF INTERESTS STATEMENT

The authors in this manuscript have no conflict of interests to declare.
