The first confirmed microlens in a globular cluster

Pietrukowicz, P; Minniti, D; Jetzer, P; Alonso-García, J; Udalski, A

Abstract: In 2000 July/August a microlensing event occurred at a distance of 2.33 arcmin from the center of the globular cluster M22 (NGC 6656), observed against the dense stellar field of the Milky Way bulge. We have used the adaptive optics system NACO at the ESO Very Large Telescope to resolve the two objects that participated in the event: the lens and the source. The position of the objects measured in 2011 July is in agreement with the observed relative proper motion of M22 with respect to the background bulge stars. Based on the brightness of the microlens components we find that the source is a solar-type star located at a distance of $6.0 \pm 1.5$ kpc in the bulge, while the lens is a $0.18 \pm 0.01$ M sun dwarf member of the globular cluster located at the known distance of $3.2 \pm 0.2$ kpc from the Sun. Based on observations collected with the ESO VLT and VISTA telescopes at Paranal Observatory (ESO Programmes 087.C-0640(A) and 179.B-2002(B), respectively), and the 1.3 m Warsaw telescope at the Las Campanas Observatory of the Carnegie Institution for Science.

ABSTRACT

In 2000 July/August a microlensing event occurred at a distance of 2.33′ from the center of the globular cluster M22 (NGC6656), observed against the dense stellar field of the Milky Way bulge. We have used the adaptive optics system NACO at the ESO Very Large Telescope to resolve the two objects that participated in the event: the lens and the source. The position of the objects measured in 2011 July is in agreement with the observed relative proper motion of M22 with respect to the background bulge stars. Based on the brightness of the microlens components we find that the source is a solar-type star located at a distance of 6.0 ± 1.5 kpc in the bulge, while the lens is a 0.18 ± 0.01 M⊙ dwarf member of the globular cluster located at the known distance of 3.2 ± 0.2 kpc from the Sun.

Subject headings: globular clusters: individual (M22) — gravitational lensing: micro — instrumentation: adaptive optics

1. Introduction

The effect of gravitational microlensing of background stars by compact objects located in globular clusters was analyzed for the first time by Paczyński (1994). He showed that

*Based on observations collected with the ESO VLT and VISTA telescopes at Paranal Observatory (ESO Programmes 087.C-0640(A) and 179.B-2002(B), respectively), and the 1.3-m Warsaw telescope at the Las Campanas Observatory of the Carnegie Institution for Science.

thanks to the usually well-known distances to the source and the lens, and transverse velocity between the populations to which the objects belong, it is possible to derive the lens mass when the event time scale is measured. Paczyński suggested to monitor globular clusters like M22 or 47 Tuc in front of the rich background of either the Galactic bulge or the Small Magellanic Cloud. According to his calculations one should detect up to a few microlensing events in one year of continuous monitoring of M22 with a 1 m class ground-based telescope. Some microlensing events detected so far toward the bulge in microlensing surveys such as OGLE (Udalski et al. 2000), MACHO (Alcock et al. 2000), and MOA (Bond et al. 2001) might be associated with globular clusters (Jetzer et al. 1998; de Luca & Jetzer 2008).

Pietrukowicz et al. (2005) presented the results of a search for erupting objects in the field of the globular cluster M22. The cluster was observed over 10 weeks in 2000-2001 with the 1.0 m Swope telescope at Las Campanas Observatory as one of the targets of the Cluster AgeS Experiment (CASE; Kaluzny et al. 2005). Besides two erupting dwarf novae they found a probable microlensing event located at \( \alpha_{2000.0} = 18^h 36^m 22.40^s, \delta_{2000.0} = -23^\circ 56' 29.4'' \), i.e., only 2.33 arcmin from the cluster center, where \( r_c = 1.33 \) and \( r_h = 3.36 \) are the core radius and half-mass radius of the cluster, respectively (taken from the 2010 version of Harris (1996) catalog). The brightness of the object increased by about 0.8 mag in \( V \) over 20 days. Around 2000 August 5 it reached a maximum of \( V = 19.1 \) magnitudes and then faded to a constant level of \( V = 19.9 \) mag. Based on its color at maximum brightness the authors excluded the possibility that the object could be a dwarf nova. They fitted a single lens model to the light curve and found that the most likely geometry of the event places the source in the Galactic bulge and the lens in the cluster. The fitted parameters are: the epoch of maximum \( t_0 = 2451759.70^{+0.33}_{-0.34} \), characteristic (Einstein) time \( t_E = 15.9^{+1.1}_{-1.1} \) days, impact parameter \( u_0 = 0.54^{+0.02}_{-0.18} \) in units of Einstein radius \( r_E \), \( V_S = 19.92^{+0.02}_{-0.02} \) mag, and \( V_L = 24.8^{+\infty}_{-4.0} \) mag, where \( V_S \) and \( V_L \) are \( V \)-band magnitudes of the source and lens, respectively. The authors assessed the mass of the lens to \( M = 0.14^{+0.10}_{-0.02} M_\odot \). Large uncertainties of the above values result from the faintness of the object and partial coverage of the event.

After many years, in some special cases it is possible to directly detect the lens, measuring its mass and the geometry of the microlensing event (e.g., Alcock et al. 2001, Kozłowski et al. 2007). In this Letter we resolve the microlensing system components based on new near-IR high-resolution images, measuring the complete geometry of the event, and the parameters of the source and lens stars. The event reported here is the first confirmed microlensing event in a globular cluster. We note that brightening episodes detected in Hubble Space Telescope (HST) images of M22 by Sahu et al. (2001) were later reexamined and interpreted either as a dwarf nova type outburst (Anderson et al. 2003) or as a result of cosmic ray double hits (Sahu et al. 2002).
2. VLT Observations and reductions

$K_s$-band observations of the M22-microlens region were obtained at the ESO Very Large Telescope (VLT) on 2011 July 17, i.e., 10.95 years after the maximum of the event. Twenty single 110 s exposures were taken using NACO at UT4, composed of the Nasmyth Adaptive Optics System (NAOS) and the High Resolution IR Camera and Spectrometer (CONICA). The detector was a 1026 $\times$ 1024 pixel SBRC InSb Alladin 3 array. We used the S27 camera of the scale $27.15$ mas pixel$^{-1}$ and the field of view of $28'' \times 28''$. The telescope jittered after each exposure according to a random pattern in an $8'' \times 8''$ box. As the guide source for adaptive optics (AO) image correction we used a $V = 14.1$ mag star located $11''36$ away from the target. The seeing during the observations ranged between $0''.69$ and $0''.99$. The data were reduced with the ESO software packages MIDAS and Eclipse. In the top panel of Figure 1 we show the combined image of the observed field. The image is affected by anisoplanatism, which degrades the point spread function (PSF) making it more elongated with increasing angular distance from the guide star. The measured full width at half maximum (FWHM) at the center of the image is $0''.11$. The M22-microlens region was also observed with VLT/NACO through the $J$ filter on 2011 April 26. Unfortunately, the measured FWHM of $0''.36$ is insufficient to detect the faint lens.

For our analysis we cut a smaller area of $600 \times 600$ pixels, covering $16''3 \times 16''3$ around the target microlens. We used DAOPHOT/ALLSTAR (Stetson 1987) to extract photometry of stars in the image. Due to relatively large difference in brightness ($\Delta K_s = 3.2$ mag) and very small separation between the source and the lens (4.59 pixels $= 124.6$ mas) the photometry was extracted in three steps. In the first step we found PSF based on selected isolated bright stars. Then using this PSF we found centroids of all stars with S/N $> 3.5$. In the second step, we removed the bright stars from the image and extracted profile photometry for residual objects, including the lens. The residual image showing the lens located slightly off the center is presented in the lower panel of Figure 1. In the final step, we re-extracted the photometry for all stars including the positions of both the source and lens.

We performed simulations in which we inserted the same pair of stars in the same location of 100 frames with subtracted stars in order to assess the errors of the positions of the two objects. The obtained mean uncertainties in pixels we converted into the unit of mas.

Standard $K_s$-band magnitudes of the stars within our field were calculated based on photometry of 51 neighboring stars detected in the near-IR VISTA Variables in the Via Lactea survey (VVV; Minniti et al. 2010). We found the source and lens to have $K_s = 17.37 \pm 0.03$ mag and $K_s = 20.57 \pm 0.09$ mag, respectively.
3. Confirmation of the microlensing event

Almost eleven (10.95) years after the microlensing event we found the lens located (123.6 ± 1.8, 15.8 ± 1.8) mas (east, south) from the source. This corresponds to a relative proper motion of the lens with respect to the source $[\mu_{\alpha}\cos\delta, \mu_{\delta}] = [11.29 \pm 0.17, -1.44 \pm 0.17]$ mas yr$^{-1}$ and its total value $\mu_{\text{rel}} = 11.38 \pm 0.24$ mas yr$^{-1}$. Based on archival HST observations Chen et al. (2004) measured the proper motion of the globular cluster M22 with respect to the background bulge stars. They obtained $[\mu_{\alpha}\cos\delta, \mu_{\delta}] = [10.19 \pm 0.20, -3.34 \pm 0.10]$ mas yr$^{-1}$ and showed that the separation between cluster and field stars is clear. They considered all stars with proper motions $< 2$ mas yr$^{-1}$ around the mean value of the cluster to be M22 members, and stars with motions $> \mu_{\alpha}\cos\delta = 5$ mas yr$^{-1}$ as mainly bulge stars.

In a vector-point diagram presented in Figure 2 we overlaid the vector measured here for the microlens on the vector for the bulge-M22 set from Chen et al. (2004). The microlens vector originates from the (0, 0) point, which refers to the cluster, and ends well within the bulge area. This confirms the geometry of the microlensing event with the source in the bulge and the lens in the globular cluster.

By fitting a model to the light curve Pietrukowicz et al. (2005) predicted that the lens is fainter than the source by $\sim 5$ mag in the $V$ band. At a distance $d_{\text{M22}} = 3.2$ kpc and mean reddening $E(B-V) = 0.38$ mag (Monaco et al. 2004) it is likely an M5 dwarf of an absolute brightness $M_V \sim 11.1$ mag. Such a star observed in the $K_s$ band would have $\sim 20.5$ mag (based on models from Brocato et al. 1998). The brightness of the faint object detected close to the target source in the VLT/NACO image is $K_s = 20.57 \pm 0.09$ mag, which is in excellent agreement.

The VLT/NACO $K_s$-band image is the only available image containing both microlensing system components. We searched the HST archives for other high-resolution images. Unfortunately, in two HST/Advanced Camera for Surveys (ACS) images taken as a part of the GO 10775 program on 2006 Apr 1 our target lies $1^\prime\!3$ off the edge. The only HST image (jb1w01010, GO 11558) covering the M22 microlens was obtained on 2010 Mar 2 in the O[III] filter centered at 5023Å and with FWHM=86Å. We checked that in this narrow-band filter all objects of similar brightness to the lens in the NACO image are below the detection limit. This supports the fact that the lens is a relatively red object.

We also checked brightness variations of the target object in recent OGLE data obtained with the 1.3 m Warsaw telescope at Las Campanas Observatory, Chile. The Optical Gravitational Lensing Experiment during its fourth phase (OGLE-IV), that started in 2010 March, observes the globular cluster M22 occasionally once or twice a week. In Figure 3 we present the $I$-band light curve of the target object in years 2010-2011. The zero point accuracy of the magnitude scale is about 0.1 mag. Constant brightness of the object within
0.2 mag corroborates that the episode of increasing brightness in 2000 July/August was a single event.

Theoretically we can estimate the probability of a chance configuration of two unrelated stars in the investigated area. We detected 342 stars in a brightness range $15.4 < K_s < 22.6$ mag in the $15'' \times 15''$ field centered on the target source. Assuming Poisson statistics this gives a density of $1.52 \pm 0.08$ stars arcsec$^{-2}$ or $0.074 \pm 0.004$ stars within 124.6 mas around the target. Eighty-two stars (corresponding to a fraction of 0.240), being fainter than $K_s = 20$ mag, could act as a potential lens in our case. The acceptable position angle of the lens ranges within $\pm 38.5$ off the M22-bulge relative proper motion direction, decreasing the chance by 0.214. If we take into account all above requirements we find $0.38\% \pm 0.02\%$ chance of such configuration at any location in the field. However, the observed position and brightness of both lens and source being in perfect agreement with the expectations unambiguously confirm the microlensing nature and geometry of the event detected in 2000.

4. Masses and distances to the microlens components

The observed $K_s$-band brightness of the lensing star and the fact that it is located in the globular cluster M22 allows us to determine its type. According to Monaco et al. (2004) M22 lies at a distance $d_{M22} = 3.2 \pm 0.2$ kpc from the Sun and has an average metallicity $[\text{Fe/H}]_{\text{CG}} = -1.68 \pm 0.15$ dex in Carretta & Gratton (1997) scale. Reddening in the direction of M22 is spread between $E(B-V) = 0.34$ and 0.42 mag (Richter et al. 1999). Using Rieke & Lebofsky (1985) relations on absorption, that $A_K = 0.112A_V$, where $A_V = 3.1E(B-V)$, we find $0.118 < A_K < 0.146$ mag for objects in M22. From this we obtain the absolute brightness of the lens $M_{Ks} = 7.91 \pm 0.16$ mag. Based on models from Brocato et al. (1998) we find the mass of the star $M_{\text{lens}} = 0.18 \pm 0.01M_\odot$ (see Figure 4).

Knowing the distance to the lensing object $d_{\text{lens}}$, its mass $M_{\text{lens}}$, relative proper motion $\mu_{\text{rel}}$ between the source and lens, and time scale of the event $t_E$ we can estimate distance to the source from the following relation

$$d_{\text{source}} = d_{\text{lens}} \left(1 - \frac{c^2 \mu_{\text{rel}}^2 t_E^2 d_{\text{lens}}}{4GM_{\text{lens}}}\right)^{-1},$$

where $G$ is the gravity constant and $c$ the speed of light. The quantities $\mu_{\text{rel}}$ and $t_E$ should be given in either heliocentric or geocentric frame. For the microlens in M22 we obtain $d_{\text{source}} = 6.0 \pm 1.5$ kpc which places the source in the Galactic bulge, as expected from the relative motion. The large errors reflect mainly the uncertainty in the estimated duration of the microlensing event.
According to Schlegel et al. (1998) the total reddening in the cluster direction amounts to $E(B - V) = 0.33$ mag. That implies that any stars located in the cluster field cannot be significantly more reddened than the cluster itself. If we assume the same absorption for the source located at 6.0 kpc as for the cluster, $A_K = 0.13$ mag, from the observed brightness of the source $K_s = 17.37$ mag we find it to be a solar-type star (Pietrinferni et al. 2006). Location of this object in a $K_s$ versus O[III]−$K_s$ diagram shown in Figure 5 supports this conclusion.

5. Summary

In the Letter we have shown that the microlensing event which occurred 2'33 from the center of the globular cluster M22 in 2000 July/August involved a $0.18 \pm 0.01 M_\odot$ dwarf of the cluster and a background solar-like star located in the Galactic bulge. Almost 11 years after the event, using high-resolution near-IR image we resolved the two microlensing components. The observed position of the source and lens stars as well as their brightness are consistent with the proposed earlier geometry of the event. Additional evidence comes from the constant brightness of the target object in the last two years (2010-2011).

We thank M. Jaroszyński for helpful discussions, and A. Gould for drawing our attention to an inconsistency in our original calculation of the source distance. Fig. 1.— $K_s$-band images of the microlens in M22. The field of view in the top panel is 20'' on a side. North is up and east is to the left. The brightest star near the SE corner of the top image served as the natural guide source for the AO image correction. The 4'' $\times$ 4'' close-up view centered on the target source is presented in the middle panel. The lower panel shows a residual image after subtracting bright stars. The faint residual object located slightly off the center is the lensing star.
Fig. 2.— Vector-point diagram of relative proper motions in the J2000 equatorial coordinate system of the bulge with respect to the globular cluster M22 (based on Chen et al. 2004). Stars that would fall inside the circle of radius 2 mas yr$^{-1}$ centered at (0, 0) are considered to be cluster members, while stars that would fall inside the circle of radius 5 mas yr$^{-1}$ centered at ($-10.19$, 3.34) mas yr$^{-1}$ are very likely bulge stars. The relative motion between the microlens system components is shown as the solid line with the small circle representing the uncertainty. The length and direction of the vector unambiguously confirm that the source belongs to the bulge, and the lens to the cluster.
Fig. 3.— OGLE-IV $I$-band light curve of the target object in years 2010-2011. Its constant brightness within 0.2 mag confirms the microlesing nature of the event in 2000 Jul/Aug.
Fig. 4.— $K_s$-band absolute brightness for dwarfs of five different masses and two metallicities, $Z=0.0002$ and 0.002, corresponding to $[\text{Fe/H}]=-2.00$ and $-0.96$ dex, respectively (data points taken from Brocato et al. 1998). The measured brightness of the lens and its uncertainty are marked with the horizontal lines.
Fig. 5.— $K_s$ vs. $O[III]$–$K_s$ diagram for 175 stars present in both VLT/NACO and HST/ACS images in the M22-microlens area. The majority of the objects are main-sequence (MS) stars of the cluster. Location of the more distant source (marked with the filled square) shows that it is fainter than the M22 MS, and consistent with a bulge MS star.
