Abstract

Many statistical applications require the forecast of a random variable of interest over several periods into the future. The sequence of individual forecasts, one period at a time, is called a path forecast, where the term *path* refers to the sequence of individual future realizations of the random variable. The problem of constructing a corresponding joint prediction region has been rather neglected in the literature so far: such a region is supposed to contain the entire future path with a prespecified probability. We develop bootstrap methods to construct joint prediction regions. The resulting regions are proven to be asymptotically consistent under a mild high-level assumption. We compare the finite-sample performance of our joint prediction regions to some previous proposals via Monte Carlo simulations. An empirical application to a real data set is also provided.

KEY WORDS: Generalized error rates; path forecast; simultaneous prediction intervals.

JEL CLASSIFICATION NOS: C14, C32, C53.

1 Introduction

When predicting a random variable, a point forecast alone is often considered insufficient. In addition, a statement about the uncertainty contained in the point forecast, as expressed by a *prediction interval*, may also be desired.

This is similar to the situation where a point estimator of a population parameter alone is considered insufficient; and where a statement about the uncertainty contained in the point estimate, as expressed by a *confidence interval*, is also desired.

Constructing a prediction interval for a random variable is inherently more difficult than constructing a confidence interval for a population parameter.

In the latter problem, typically, a central limit theorem can be applied to argue that an estimator of the parameter has, approximately, a normal distribution for large sample sizes. This allows for the construction of standard, normal-theory confidence intervals described in any basic statistics text book. The use of bootstrap methods as an alternative is ‘only’ motivated by higher-order considerations: standard methods already result in confidence intervals that are consistent, that is, have coverage probability equal to the nominal level $1 - \alpha$ asymptotically.

In the former problem, no central limit theorem can be applied to argue that the difference between a point forecast and the random variable of interest has, approximately, a normal distribution for large sample sizes. Therefore, standard normal-theory prediction intervals are only valid under restrictive parametric assumptions. The use of bootstrap methods as an alternative is motivated by first-order considerations already: they result in prediction intervals that are consistent under very general assumptions where standard, normal-theory prediction intervals fail.

How to apply the bootstrap to construct prediction intervals that are not only asymptotically consistent but also have good finite-sample properties is not a trivial problem. But it can be considered solved by now to a satisfactory degree; for example, see [De Gooijer and Hyndman \(2006, Section 12\)](#) for an overview.

The discussion up to this point only applies to a single (future) random variable. In many applications, however, a random variable of interest is predicted up to H periods into the future. For example, one might predict future inflation for the next $H = 12$ months. A *path* refers to the sequence of future realizations 1 to H periods into the future. A *path forecast* refers to the sequence of corresponding forecasts 1 to H periods into the future.

On the one hand, one can construct H marginal prediction intervals by using a given method to construct a prediction interval repeatedly, one period at a time. But, by design, probability statements then only apply marginally, one period at a time: the prediction interval at a specific horizon h , for some $1 \leq h \leq H$, will contain the random variable h periods into the future with prespecified probability $1 - \alpha$.

On the other hand, a more general problem is the construction of a *joint prediction region* that will contain the entire future path with the desired probability $1 - \alpha$. For example, if one would like to know with probability $1 - \alpha$ how high inflation might rise over the next $H = 12$ months, one needs to construct a joint prediction region for the future path at level $1 - \alpha$ as

opposed to stringing together 12 marginal prediction intervals, each one at level $1 - \alpha$.

It should be clear that stringing together marginal prediction intervals for horizons $h = 1$ up to $h = H$, each one at level $1 - \alpha$, will not result in a joint prediction region that contains the entire future path with probability $1 - \alpha$. Instead, apart from pathological cases, the joint coverage probability will be strictly less than $1 - \alpha$, and decreasing in H . Denote by E_h the event that the random variable at period h in the future will fall into its prediction interval. If the events $\{E_h\}_{h=1}^H$ are independent of each other, then stringing together marginal prediction intervals results in a joint prediction region that will contain the entire future path with probability $(1 - \alpha)^H$ only.

In practice, the events $\{E_h\}_{h=1}^H$ are typically not independent of each other. Stringing together marginal prediction intervals then results in a joint prediction region that will contain the entire future path with probability somewhere between $\max\{0, 1 - H \cdot \alpha\}$ and $1 - \alpha$, where the lower bound is obtained by Bonferroni's inequality. The exact probability is a function of the dependence structure of the events $\{E_h\}_{h=1}^H$.

Unfortunately, the method of stringing together marginal prediction intervals at level $1 - \alpha$ for horizons $h = 1$ up to $h = H$ is still widely in use, such as in the fan charts for GDP growth and CPI inflation published by the Bank of England and the Central Bank of Norway.¹

Using Bonferroni's inequality, a conservative joint prediction region can be constructed by stringing together marginal prediction intervals at level $1 - \alpha/H$ instead of at level $1 - \alpha$; for example, such an approach is already mentioned by Lütkepohl (1991, Section 2.2.3). But since Bonferroni's inequality is generally crude, such an approach results in joint confidence regions whose coverage probability is generally (much) above $1 - \alpha$ and that are thus unnecessarily wide, losing to a loss of information.

The construction of joint prediction regions for future paths of a random variable of interest with coverage probability $1 - \alpha$ has been rather neglected in the forecasting literature so far. Two notable exceptions are Jordà and Marcellino (2010) and Staszewska-Bystrova (2011). The former work proposes an 'asymptotic' method that relies on the overly strong assumption that forecast errors have, approximately, a normal distribution. The latter work proposes a bootstrap method that is of heuristic nature only. Therefore, neither of the proposed methods might be entirely safe to use in practice.

In this paper, we propose a bootstrap method to construct joint predictions regions that are proven to contain future paths of a random variable of interest with probability $1 - \alpha$, at least asymptotically, under a mild high-level assumption.

In addition, we also consider the more general problem of constructing joint prediction regions that will only contain all elements of future paths up to a small number of them with probability $1 - \alpha$; we will denote this small number by $k - 1$. If the maximum forecast horizon H is large, the applied researcher may deem the original criterion (namely, that all elements of the future path must be contained in the joint prediction region with probability $1 - \alpha$) as

¹ Several examples can be found at <http://www.bankofengland.co.uk/publications/inflationreport/> and <http://www.norges-bank.no/english/inflationreport/>.

too strict. For example, when $H = 24$, it may be deemed acceptable that up to $k - 1 = 2$ elements of the future path may fall outside the joint prediction region; thus requiring that ‘only’ at least 22 of the 24 elements — or at least 90% of the 24 elements — of the future path be contained in the joint prediction region with probability $1 - \alpha$. The choice of k must be made by the applied researcher, not by the statistician. But it will be useful to the applied researcher to have a method available that can handle any desired value of k . In particular, the choice $k = 1$ yields a ‘standard’ joint prediction region that must contain all elements of a future path with probability $1 - \alpha$.

The remainder of the paper is organized as follows. Section 2 contains some background results that are useful for setting the stage. Section 3 describes our method to construct joint prediction regions and compares it to some previous proposals in the literature. Section 4 studies finite-sample performance via Monte Carlo simulations. Section 5 provides an empirical application to real data. Finally, Section 6 contains some concluding remarks.

2 Background Results

Our motivating problem is the construction of a joint prediction region for a future path of a random variable of interest. However, the proposed methodology applies more generally to the construction of a joint prediction region of an arbitrary random vector that has not been observed yet.

In explaining the methodology, it will be convenient to start with the special case of a single random variable that has not been observed yet.

2.1 Single Forecast

First, consider a single random variable y with mean $\mu := \mathbb{E}(y)$. This special case makes it easier to explain some fundamental concepts before considering the more general case of a random vector with H elements.

One may wish to predict y or to estimate μ . Denote the forecast of y by \hat{y} and the estimator of μ by $\hat{\mu}$. Often times, the two are actually the same, that is $\hat{y} = \hat{\mu}$; for example, in the context of linear regression models under quadratic loss. Therefore, in terms of a (point) forecast of y compared to a (point) estimate of μ , there often is no difference at all.

But what if one desires an ‘uncertainty interval’ in addition? Such an interval should contain the random variable y or its mean μ , respectively, with a prespecified probability $1 - \alpha$. Now the two solutions are fundamentally different and the former interval will have to be wider due to the additional randomness contained in the random variable y compared to its mean μ . To make this distinction apparent in the notation, we prefer to call the solution to the former problem a *prediction interval* and the solution to the latter problem a *confidence interval*. In doing so, we are in agreement with [De Gooijer and Hyndman \(2006, p.460\)](#):

Unfortunately, there is still some confusion in terminology with many authors by “confidence interval” instead of “prediction interval”. A confidence interval is for a

model parameter, whereas a prediction interval is for a random variable. Almost always, forecasters will want prediction intervals — intervals which contain the true values of future observations with [a] specified probability.

2.2 Path Forecast

More generally, consider a random vector $Y := (y_1, \dots, y_H)'$ of interest with mean $\boldsymbol{\mu} := (\mu_1, \dots, \mu_H)' = \mathbb{E}(Y)$. For the purposes of this paper, Y will typically correspond to the values of a random variable 1 to H periods into the future; that is, to a future *path* of a random variable. But the discussion below applies to any random vector. The underlying probability mechanism is denoted by \mathbb{P} .

One can wish to predict Y or to estimate $\boldsymbol{\mu}$. Denote the forecast of Y by \hat{Y} and the estimator of $\boldsymbol{\mu}$ by $\hat{\boldsymbol{\mu}}$. (When Y corresponds to a future path of a random variable, \hat{Y} is also called a *path forecast*.) Again, often, the two are actually the same, that is, $\hat{Y} = \hat{\boldsymbol{\mu}}$; for example, in the context of linear regression models under quadratic loss. Therefore, again, in terms of a (point) forecast of Y compared to a (point) estimate of $\boldsymbol{\mu}$, there often is no difference at all.

What if one desires the extension of an ‘uncertainty interval’ for a univariate quantity to a ‘(joint) uncertainty region’ for a multivariate quantity? In the most stringent case, such a region should contain the *entire* random vector Y or its mean $\boldsymbol{\mu}$, respectively, with a prespecified probability $1 - \alpha$. Again, the two solutions are fundamentally different and the former region will have to be larger (in volume) due to the additional randomness contained in Y compared to its mean $\boldsymbol{\mu}$.

A potential complication with joint regions arises when uncertainty statements concerning the individual components y_h or μ_h , respectively, are desired. For example, this is typically the case when a joint prediction region for Y is to be constructed in addition to a path forecast \hat{Y} . One desires lower and upper bounds for each component y_h in such a manner that the entire vector Y be contained in the implied rectangle with probability $1 - \alpha$. This is a trivial task if the underlying joint prediction region is already of rectangular form. But this is not true for all methods to compute joint regions; many methods result in regions of elliptical form instead. The most prominent example is the Scheffé joint region, dating back to [Scheffé \(1953, 1959\)](#).

The Scheffé joint confidence region for $\boldsymbol{\mu}$ is obtained by inverting the classical F -test. Let $\hat{\boldsymbol{\Sigma}}(\hat{\boldsymbol{\mu}})$ denote an estimated covariance matrix of $\hat{\boldsymbol{\mu}}$. Then the joint confidence region is given by

$$\text{JCR} := \{ \boldsymbol{\mu}_0 : (\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0)' [\hat{\boldsymbol{\Sigma}}(\hat{\boldsymbol{\mu}})]^{-1} (\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}_0) \leq \chi_{H,1-\alpha}^2 \}, \quad (2.1)$$

where $\chi_{H,1-\alpha}^2$ denotes the $1 - \alpha$ quantile of the chi-square distribution with H degrees of freedom. The use of this joint confidence region is usually justified by a central limit theorem implying an approximate multivariate normal distribution of $\hat{\boldsymbol{\mu}}$ with mean $\boldsymbol{\mu}$. Such a central limit theorem will hold under mild regularity conditions; for example, see [White \(2001\)](#).

The Scheffé joint prediction region for Y is obtained similarly. Define the vector of prediction errors by $\hat{U} := \hat{Y} - Y$ and let $\hat{\boldsymbol{\Sigma}}(\hat{U})$ denote an estimated covariance matrix of this vector. Then

the joint prediction region is given by

$$\text{JPR} := \{X : (\widehat{Y} - X)' [\widehat{\Sigma}(\widehat{Y})]^{-1} (\widehat{Y} - X) \leq \chi_{H,1-\alpha}^2\} . \quad (2.2)$$

The use of this joint prediction region is only justified if \widehat{U} has approximately a multivariate normal distribution with mean zero. This is a strong additional assumption, which is often violated in practice. A central limit theorem can typically be applied to argue that an *estimator* has, approximately, a normal distribution for large sample sizes. But a central limit theorem can never be applied to argue that a *forecast error has*, approximately, a normal distribution for large sample sizes. This point is illustrated via a simple example in Remark 3.2 below.

If the joint region is of elliptical form and statements concerning the individual components are desired, the joint region has to be ‘projected’ on the axes of \mathbb{R}^H . This action implies a *larger* rectangular joint region: namely, the smallest rectangle, with sides parallel to the axes of \mathbb{R}^H , that contains the original elliptical region. As a result, if the elliptical region has joint coverage probability $1 - \alpha$, then the implied rectangular region has joint coverage probability larger than $1 - \alpha$. Therefore, such a projection method is generally overly conservative. If statements concerning the individual components are desired, it is advantageous to construct ‘direct’ rectangular joint regions instead.

Remark 2.1. It is useful to illustrate these concepts in simple, parametric setup. Assume $Y := (Y_1, Y_2)' \sim N(\boldsymbol{\mu}, \mathbf{I}_2)$, where $\boldsymbol{\mu} := (\mu_1, \mu_2)'$ and \mathbf{I}_2 is the identity matrix of dimension two. Therefore, Y_1 and Y_2 are independent with $Y_h \sim N(\mu_h, 1)$. The goal is to construct a joint confidence region for $\boldsymbol{\mu}$. The point estimator for $\boldsymbol{\mu}$ is simply given by the observed random vector, that is, $\widehat{\boldsymbol{\mu}} := Y$.

The Scheffé joint confidence region is obtained by inverting the classical F -test. It is a circle centered at Y with radius $\sqrt{\chi_{2,1-\alpha}^2}$, where $\chi_{2,1-\alpha}^2$ denotes the $1 - \alpha$ quantile of the chi-square distribution with two degrees of freedom. For example, when $\alpha = 0.05$, the radius is $\sqrt{5.99} \approx 2.45$. The implied rectangular joint confidence region, obtained by projecting the circle on the two axes, is a square with center Y and (approximate) half length 2.45.

On the other hand, a ‘direct’ rectangular joint confidence region is given by

$$[Y_1 \pm d_{2,1-\alpha}] \times [Y_2 \pm d_{2,1-\alpha}] ,$$

where $d_{2,1-\alpha}$ is the $1 - \alpha$ quantile of the random variable $\max\{|Y_1 - \mu_1|, |Y_2 - \mu_2|\}$. These quantiles are not commonly tabulated, but can be easily simulated to arbitrary precision. For example, when $\alpha = 0.05$, then $d_{2,0.95} \approx 2.24$.

The ‘direct’ rectangular joint confidence region is thus a square with center Y and (approximate) half length 2.24. Therefore, it is smaller than the implied rectangular joint confidence region by the Scheffé method.

The Scheffé region itself has a smaller volume than the ‘direct’ rectangular region when $\alpha = 0.05$, namely

$$2.45^2 \cdot \pi \approx 18.86 < 20.07 \approx (2 \cdot 2.24)^2 .$$

But when a rectangular region is needed in the end, projecting the Scheffé region on the axes results in a larger region compared to the ‘direct’ rectangular region. An illustration is provided in Figure 1. ■

Figure 1: An illustration of Remark 2.1. One observes $\hat{\boldsymbol{\mu}} = Y = (0.0, 0.0)$ and wishes to construct a joint confidence region for $\boldsymbol{\mu}$ with confidence level $1 - \alpha = 0.95$. The solid ellipse is the Scheffé joint confidence region: a circle with radius 2.45. The solid rectangle is the implied (that is, projected on the axes) rectangular joint confidence region: a square with half length 2.45. The dashed rectangle is the ‘direct’ rectangular joint confidence region: a square with half length 2.24.

The stringent joint regions discussed so far control the probability of containing the entire vector of interest to be (at least) equal to $1 - \alpha$. Equivalently, they control the probability of missing at least one component of the vector to be (at most) equal to α . Borrowing from the multiple testing literature, the latter probability can be termed the *familywise error rate* (FWE); for example, see Romano et al. (2008). So for a joint confidence region (JCR) for $\boldsymbol{\mu}$,

$$\text{FWE} := \mathbb{P}\{\text{At least one of the } \mu_h \text{ not contained in the JCR}\}, \quad (2.3)$$

whereas for a joint prediction region (JPR) for Y ,

$$\text{FWE} := \mathbb{P}\{\text{At least one of the } y_h \text{ not contained in the JPR}\} . \quad (2.4)$$

Jordà et al. (2010, Section 2.2) argue that controlling the FWE can be too strict:

For example, in a prediction of a path of monthly inflation over the next two years, control of the FWE would result in rejection of such paths as when the trajectory of inflation is [almost] correctly predicted for 23 periods but the prediction of the last month is particularly poor.

The decision whether the FWE is too strict or not in a given application has to be made by the applied researcher, not by the statistician. It is the job of the statistician to provide the applied researcher with an alternative tool in case his decision is against control of the FWE. In such a case, we suggest to use the *generalized familywise error rate* (k -FWE).

For a joint confidence region (JCR) for μ ,

$$k\text{-FWE} := \mathbb{P}\{\text{At least } k \text{ of the } \mu_h \text{ not contained in the JCR}\} , \quad (2.5)$$

whereas for a joint prediction region (JPR) for Y ,

$$k\text{-FWE} := \mathbb{P}\{\text{At least } k \text{ of the } y_h \text{ not contained in the JPR}\} . \quad (2.6)$$

As a special case, the choice $k = 1$ gives back the FWE. On the other hand, any choice $k \geq 2$ results in a less stringent error rate.

As will be discussed in Section 3, the larger the value of k , the smaller the resulting joint region. Consequently, by being willing to miss a small number of components in the joint region, the applied researcher can obtain more precise bounds in return.

Since the number of components, H , is known, control of the k -FWE immediately gives control on the probability of the proportion of components not contained in the joint region. Take the example of a path forecast with $H = 24$ components, as when predicting monthly inflation for the next two years. Then the choice $k = 3$ allows for a proportion of missed components up to 10%. This is because one or two missed components, out of the $H = 24$, do not constitute a violation of the 3-FWE criterion, but three or more missed components do.

The next section details how the k -FWE, which includes the FWE as a special case, can be controlled in practice. It only does this in the context of a joint prediction region for Y . The method is similar in the context of a joint confidence region for μ and is detailed in Romano and Wolf (2005, 2007) already.

Since the method is based on quantiles of random variables whose cumulative distribution function may not be invertible, the following remark is in order.

Remark 2.2. If the cumulative distribution function of a random variable is not invertible, then its quantiles are not necessarily uniquely defined. To be specific, we adopt the following definition for quantiles in this paper.

Let X be a random variable with cumulative distribution function $F(\cdot)$. Then, for $\lambda \in (0, 1)$, the λ quantile of (the distribution of) X is defined as $\inf\{x : F(x) \geq \lambda\}$. ■

3 Joint Prediction Regions Based on k -FWE Control

The goal is to construct a joint prediction region for a future path that controls the k -FWE, for an arbitrary integer $1 \leq k < H$. In particular, the special choice $k = 1$ corresponds to control of the FWE.

Any formal analysis has to be put into a suitable framework. To this end, we borrow some notation from [Jordà et al. \(2010\)](#). We start out by discussing the case of a univariate time series, which simplifies the notation and makes it easier to focus on the methodology.

3.1 Univariate Time Series

One observes a univariate time series $\{y_1, \dots, y_T\}$ generated from a true probability mechanism \mathbb{P} and wishes to predict the future path $Y_{T,H} := (y_{T+1}, \dots, y_{T+H})'$. At time t , denote a forecast h periods ahead by $\hat{y}_t(h)$. Then a path forecast for $Y_{T,H}$ is given by $\hat{Y}_T(H) := (\hat{y}_T(1), \dots, \hat{y}_T(H))'$. Denote the vector of prediction errors by $\hat{U}_T(H) := (\hat{u}_T(1), \dots, \hat{u}_T(H))' := \hat{Y}_T(H) - Y_{T,H}$. Finally, $\hat{\sigma}_T(h)$ denotes a prediction standard error, that is, a standard error for $\hat{u}_T(h)$: it is an estimator of the unknown standard deviation of the random variable $\hat{u}_T(h)$.

We further assume a generic method to compute a vector of bootstrap prediction errors $\hat{U}_T^*(H) := (\hat{u}_T^*(1), \dots, \hat{u}_T^*(H))'$, based on artificial bootstrap data $\{y_1^*, \dots, y_T^*, y_{T+1}^*, \dots, y_{T+H}^*\}$ generated from an estimated probability mechanism $\hat{\mathbb{P}}_T$. Such bootstrap forecast errors can be computed in many different ways. We shall not enter this debate here; the goal is to provide a generic procedure to construct a joint prediction region where application-specific details are up to the applied researcher. Finally, $\hat{\sigma}_T^*(h)$ denotes a bootstrap prediction standard error, that is, a standard error for $\hat{u}_T^*(h)$.

We now briefly illustrate these concepts. The observed data are $\{y_1, \dots, y_T\}$. The applied researcher selects a suitable ‘null’ model, fits it to the data, and then uses the fitted model to make the predictions $\hat{y}_T(h)$, for $h = 1, \dots, H$. To be specific, assume he uses an ARIMA model. The fitted model also provides prediction standard errors $\hat{\sigma}_T(h)$. Next, the applied researcher generates bootstrap data $\{y_1^*, \dots, y_T^*, y_{T+1}^*, \dots, y_{T+H}^*\}$. To this end, he can use a parametric bootstrap, based on the ARIMA model fitted from the original data; this might be a preferred approach if he believes that his null model is correctly specified. Alternatively, he can use a nonparametric time series bootstrap (say a blocks bootstrap or a sieve bootstrap); this would be a suitable approach if he believes that his null model might be misspecified.² Not making use of the stretch $\{y_{T+1}^*, \dots, y_{T+H}^*\}$, he computes forecasts $\hat{y}_T^*(h)$ and prediction standard errors $\hat{\sigma}_T^*(h)$. Finally, he computes $\hat{u}_T^*(h) := \hat{y}_T^*(h) - y_{T+h}^*$.

Our high-level assumption below is based on the two vectors of *standardized prediction errors* $\hat{S}_T(H) := (\hat{u}_T(1)/\hat{\sigma}_T(1), \dots, \hat{u}_T(H)/\hat{\sigma}_T(H))'$ and $\hat{S}_T^*(H) := (\hat{u}_T^*(1)/\hat{\sigma}_T^*(1), \dots, \hat{u}_T^*(H)/\hat{\sigma}_T^*(H))'$, respectively. Denote the probability law under \mathbb{P} of $\hat{S}_T(H)|y_T, y_{T-1}, \dots$ by \hat{J}_T . Also denote the probability law under $\hat{\mathbb{P}}_T$ of $\hat{S}_T^*(H)|y_T^*, y_{T-1}^*, \dots$ by \hat{J}_T^* . In the asymptotic framework, T tends

²For an overview of nonparametric time series bootstrap methods, the reader is referred to [Bühlmann \(2002\)](#), [Lahiri \(2003\)](#), and [Politis \(2003\)](#).

to infinity whereas H remains fixed.

Assumption 3.1. \widehat{J}_T converges in distribution to a non-random continuous limit law \widehat{J} . Furthermore, \widehat{J}_T^* consistently estimates this limit law: $\rho(\widehat{J}_T, \widehat{J}_T^*) \rightarrow 0$ in probability, for any metric ρ metrizing weak convergence.

Expressed in words, Assumption 3.1 states that, as the sample size T increases, the conditional distribution of the vector of standardized bootstrap prediction errors $\widehat{S}_T^*(H)$ becomes a more and more reliable approximation to the (unknown) conditional distribution of the vector of true standardized prediction errors $\widehat{S}_T(H)$.

We next specify the forms of the joint prediction regions for $Y_{T,H}$, first for the two-sided case and then for the one-sided case.

Some further notation is required. Suppose $X := (x_1, \dots, x_H)'$ is a vector with H components. First, for $k \in \{1, \dots, H\}$, $k\text{-max}(X)$ returns the k th-largest value of the x_h . So, if the elements x_h , $1 \leq h \leq H$, are ordered as $x_{(1)} \leq \dots \leq x_{(H)}$, then $k\text{-max}(X) := x_{(H-k+1)}$. Second, for $k \in \{1, \dots, H\}$, $k\text{-min}(X)$ returns the k th-smallest value of the x_h ; that is, $k\text{-min}(X) := x_{(k)}$. Third, $|X|$ denotes the vector $(|x_1|, \dots, |x_H|)'$.

Let $d_{|\cdot|, 1-\alpha}^{k\text{-max}}$ denote the $1 - \alpha$ quantile of the random variable $k\text{-max}(|\widehat{S}_T(H)|)$. Then a two-sided joint prediction region for $Y_{T,H}$ that controls the k -FWE in finite samples is given by

$$[\widehat{y}_T(1) \pm d_{|\cdot|, 1-\alpha}^{k\text{-max}} \cdot \widehat{\sigma}_T(1)] \times \dots \times [\widehat{y}_T(H) \pm d_{|\cdot|, 1-\alpha}^{k\text{-max}} \cdot \widehat{\sigma}_T(H)] . \quad (3.1)$$

The implication is that the probability that the region (3.1) will contain at least $H - k + 1$ elements of $Y_{T,H}$ is equal to (at least) $1 - \alpha$ in finite samples. This property follows immediately from the definition of the multiplier $d_{|\cdot|, 1-\alpha}^{k\text{-max}}$.

The problem is that the ideal region (3.1) is not feasible, since the multiplier $d_{|\cdot|, 1-\alpha}^{k\text{-max}}$ is unknown. This multiplier has to be estimated in practice by $d_{|\cdot|, 1-\alpha}^{k\text{-max},*}$, which is defined as the $1 - \alpha$ quantile of the random variable $k\text{-max}(|\widehat{S}_T^*(H)|)$. This quantile can typically not be derived analytically, but it can be simulated to arbitrary precision from a sufficiently large number of bootstrap samples; see Algorithm 3.1 below.

Then a two-sided joint prediction region for $Y_{T,H}$ that controls the k -FWE asymptotically is given by

$$[\widehat{y}_T(1) \pm d_{|\cdot|, 1-\alpha}^{k\text{-max},*} \cdot \widehat{\sigma}_T(1)] \times \dots \times [\widehat{y}_T(H) \pm d_{|\cdot|, 1-\alpha}^{k\text{-max},*} \cdot \widehat{\sigma}_T(H)] . \quad (3.2)$$

The implication is that the probability that the region (3.2) will contain at least $H - k + 1$ elements of $Y_{T,H}$ is equal to (at least) $1 - \alpha$ asymptotically.

The modifications to the one-sided case are as follows; we only present the feasible regions.

Let $d_{1-\alpha}^{k\text{-max},*}$ denote the $1 - \alpha$ quantile of the random variable $k\text{-max}(\widehat{S}_T^*(H))$. Then a one-sided lower joint prediction region for $Y_{T,H}$ that controls the k -FWE asymptotically is given by

$$[\widehat{y}_T(1) - d_{1-\alpha}^{k\text{-max},*} \cdot \widehat{\sigma}_T(1), \infty) \times \dots \times [\widehat{y}_T(H) - d_{1-\alpha}^{k\text{-max},*} \cdot \widehat{\sigma}_T(H), \infty) . \quad (3.3)$$

Let $d_{\alpha}^{k\text{-min},*}$ denote the α quantile of the random variable $k\text{-min}(\widehat{S}_T^*(H))$. Then a one-sided upper joint prediction region for $Y_{T,H}$ that controls the k -FWE asymptotically is given by

$$(-\infty, \widehat{y}_T(1) - d_{\alpha}^{k\text{-min},*} \cdot \widehat{\sigma}_T(1)] \times \dots \times (-\infty, \widehat{y}_T(H) - d_{\alpha}^{k\text{-min},*} \cdot \widehat{\sigma}_T(H)] . \quad (3.4)$$

Note here that $d_\alpha^{k-\min,*}$ is generally a negative number so that, for each horizon h , the upper end of the corresponding interval is indeed larger than the forecast $\hat{y}_T(h)$.

As is clear from the definitions, both the multipliers $d_{|\cdot|,1-\alpha}^{k-\max,*}$ and $d_{1-\alpha}^{k-\max,*}$ are monotonically decreasing in k , while the multiplier $d_\alpha^{k-\min,*}$ is monotonically increasing in k . Consequently, the larger the value of k , the smaller in volume are the regions (3.2)–(3.4); for an illustration, see Subsection 5.1. (When we speak of ‘volume’ for the one-sided regions (3.3)–(3.4), we implicitly refer to the relevant lower or upper ‘half volumes’, since the entire volume is always infinite, of course.)

The following proposition formally establishes the asymptotic validity of these feasible bootstrap joint prediction regions.

Proposition 3.1. *Under Assumption 3.1, each of the joint prediction regions (JPRs) (3.2)–(3.4) for $Y_{T,H}$ satisfies*

$$\limsup_{T \rightarrow \infty} k\text{-FWE} \leq \alpha, \quad (3.5)$$

where

$$k\text{-FWE} := \mathbb{P}\{\text{At least } k \text{ of the } y_{T+h} \text{ not contained in the JPR}\}. \quad (3.6)$$

Proof: We prove the stated result for the joint prediction region (3.3). The proofs for the joint prediction regions (3.2) and (3.4) are completely analogous.

Let \hat{L}_T denote a random variable with distribution \hat{J}_T and let \hat{L} denote a random variable with distribution \hat{J} . By Assumption 3.1 and the continuous mapping theorem, $k\text{-max}(\hat{L}_T)$ converges weakly to $k\text{-max}(\hat{L})$, whose distribution is continuous. Our notation implies that the conditional sampling distribution under \mathbb{P} of $k\text{-max}(\hat{S}_T(H))$ is identical to the distribution of $k\text{-max}(\hat{L}_T)$. By similar reasoning, the conditional sampling distribution under $\hat{\mathbb{P}}_T$ of $k\text{-max}(\hat{S}_T^*(H))$ also converges weakly to the distribution of $k\text{-max}(\hat{L})$. To then show that

$$\mathbb{P}\{k\text{-max}(\hat{S}_T(H)) \leq d_{1-\alpha}^{k-\max,*}\} \rightarrow 1 - \alpha \quad (3.7)$$

is similar to the proof of Theorem 1 of [Beran \(1984\)](#).

Since by definition of the k -FWE and the construction of the joint prediction region (3.3),

$$k\text{-FWE} = 1 - \mathbb{P}\{k\text{-max}(\hat{S}_T(H)) \leq d_{1-\alpha}^{k-\max,*}\}, \quad (3.8)$$

the proof that the stated result (3.5) holds for the joint prediction region (3.3) now follows immediately from (3.7). ■

The following algorithm details how to compute the three multipliers $d_{|\cdot|,1-\alpha}^{k-\max,*}$, $d_{1-\alpha}^{k-\max,*}$, and $d_\alpha^{k-\min,*}$ in practice. The algorithm assumes a generic bootstrap method, chosen by the applied researcher, to generate bootstrap data and standardized bootstrap prediction errors. In particular, such a bootstrap method is based on an estimated probability mechanism $\hat{\mathbb{P}}_T$.

Algorithm 3.1 (Computation of the JPR Multipliers; Univariate Case).

1. Generate bootstrap data $\{y_1^*, \dots, y_T^*, y_{T+1}^*, \dots, y_{T+H}^*\}$ from $\hat{\mathbb{P}}_T$.

2. Not making use of the stretch $\{y_{T+1}^*, \dots, y_{T+H}^*\}$, compute forecasts $\widehat{y}_T^*(h)$ and prediction standard errors $\widehat{\sigma}_T^*(h)$.
3. Compute bootstrap prediction errors $\widehat{u}_T^*(h) := \widehat{y}_T^*(h) - y_{T+h}^*$.
4. Compute standardized bootstrap prediction errors $\widehat{s}_T^*(h) := \widehat{u}_T^*(h)/\widehat{\sigma}_T^*(h)$ and let $\widehat{S}_T^*(H) := (\widehat{s}_T^*(1), \dots, \widehat{s}_T^*(H))'$.
5. Compute $k\text{-max}_{|\cdot|}^* := k\text{-max}(|\widehat{S}_T^*(H)|)$, $k\text{-max}^* := k\text{-max}(\widehat{S}_T^*(H))$, and $k\text{-min}^* := k\text{-min}(\widehat{S}_T^*(H))$.
6. Repeat this process B times, resulting in statistics $\{k\text{-max}_{|\cdot|,1}^*, \dots, k\text{-max}_{|\cdot|,B}^*\}$, $\{k\text{-max}_1^*, \dots, k\text{-max}_B^*\}$, and $\{k\text{-min}_1^*, \dots, k\text{-min}_B^*\}$.
7. Compute the corresponding empirical quantiles:
 - 7.1 $d_{|\cdot|,1-\alpha}^{k\text{-max},*}$ is the empirical $1 - \alpha$ quantile of the statistics $\{k\text{-max}_{|\cdot|,1}^*, \dots, k\text{-max}_{|\cdot|,B}^*\}$.
 - 7.2 $d_{1-\alpha}^{k\text{-max},*}$ is the empirical $1 - \alpha$ quantile of the statistics $\{k\text{-max}_1^*, \dots, k\text{-max}_B^*\}$.
 - 7.3 $d_\alpha^{k\text{-min},*}$ is the empirical α quantile of the statistics $\{k\text{-min}_1^*, \dots, k\text{-min}_B^*\}$.

In an application, the number B of bootstrap samples should be chosen as large as possible; at the very least $B \geq 1,000$.

Remark 3.1. Proposition 3.1 only addresses asymptotic consistency. It does not address finite-sample performance. To ensure best-possible finite-sample performance the applied researcher should make an effort to match the bootstrap distribution \widehat{J}_T^* as close as possible to the true distribution \widehat{J}_T . How this is to be done in detail depends on the particular bootstrap method chosen by the applied researcher. Many papers have been written on this problem already; for example, see [De Gooijer and Hyndman \(2006, Section 12\)](#).

We confine ourselves to the general statement that model parameters that have to be estimated from the original data $\{y_1, \dots, y_T\}$ to compute the forecasts $\widehat{y}_T(h)$ and the prediction standard errors $\widehat{\sigma}_T(h)$ should be re-estimated from the bootstrap data $\{y_1^*, \dots, y_T^*\}$ to compute the forecasts $\widehat{y}_T^*(h)$ and the prediction standard errors $\widehat{\sigma}_T^*(h)$. It may be tempting, say in order to save computing time, to simply use the estimated model parameters from the original data $\{y_1, \dots, y_T\}$ to compute the forecasts $\widehat{y}_T^*(h)$ and the prediction standard errors $\widehat{\sigma}_T^*(h)$. But such an approach does not reflect the fact that the true model parameters are unknown and generally leads to bootstrap prediction errors that are too small in magnitude. ■

3.2 Multivariate Time Series

Compared to the special case of a univariate time series, the methodology does not change in any fundamental way in the general case of a multivariate time series, as in the case of VAR forecasting. Mainly, the notation becomes more complex.

One observes a time series $\{Z_1, \dots, Z_T\}$, where $Z_t := (z_{1,t}, \dots, z_{K,t})'$, generated from a true probability mechanism \mathbb{P} and wishes to predict the next stretch of H observations for a particular component of Z_t . Assume without loss of generality that one wishes to predict the first component of Z_t and write $Z_t := (y_t, z_{2,t}, \dots, z_{K,t})'$.

In this more general case, the forecast of y_{T+h} , denoted by $\widehat{y}_T(h)$ again, will be a function

of $\{Z_1, \dots, Z_T\}$ instead of a function of $\{y_1, \dots, y_T\}$ only; and similarly for the corresponding prediction standard error $\widehat{\sigma}_T(h)$.

Artificial bootstrap data $\{Z_1^*, \dots, Z_T^*, Z_{T+1}^*, \dots, Z_{T+H}^*\}$ are generated from an estimated probability mechanism $\widehat{\mathbb{P}}_T$. In particular, K -variate VAR models appear a popular choice to this end with applied researchers; more generally, SVAR, VECM, or SVECM models can also be used; for example, see Lütkepohl (2005).

Denote $Z_t^* := (y_t^*, z_{2,t}^*, \dots, z_{K,t}^*)'$. The forecast of y_{T+h}^* , denoted by $\widehat{y}_T^*(h)$ again, will be a function of $\{Z_1^*, \dots, Z_T^*\}$ instead of a function of $\{y_1, \dots, y_T\}$ only; and similarly for the corresponding prediction standard error $\widehat{\sigma}_T^*(h)$.

Assumption 3.1 continues to be based on the two vectors of standardized prediction errors $\widehat{S}_T(H) := (\widehat{u}_T(1)/\widehat{\sigma}_T(1), \dots, \widehat{u}_T(H)/\widehat{\sigma}_T(H))'$ and $\widehat{S}_T^*(H) := (\widehat{u}_T^*(1)/\widehat{\sigma}_T^*(1), \dots, \widehat{u}_T^*(H)/\widehat{\sigma}_T^*(H))'$, respectively. Only that now, more generally, \widehat{J}_T denotes the probability law under \mathbb{P} of $\widehat{S}_T(H)|Z_T, Z_{T-1}, \dots$; and \widehat{J}_T^* denotes the probability law under $\widehat{\mathbb{P}}_T$ of $\widehat{S}_T^*(H)|Z_T^*, Z_{T-1}^*, \dots$.

Having detailed how the quantities of interest are defined and computed in the more general case, the methodology outlined in the case of a univariate time series applies verbatim.

The various forms of the joint prediction regions are still given by (3.2)–(3.4) and Proposition 3.1 continues to hold.

The following algorithm details how to compute the three multipliers. The following algorithm details how to compute the three multipliers $d_{|\cdot|, 1-\alpha}^{k-\max,*}$, $d_{1-\alpha}^{k-\max,*}$, and $d_\alpha^{k-\min,*}$ in practice. The algorithm assumes a generic bootstrap method, chosen by the applied researcher, to generate bootstrap data and standardized bootstrap prediction errors. In particular, such a bootstrap method is based on an estimated probability mechanism $\widehat{\mathbb{P}}_T$.

Algorithm 3.2 (Computation of the JPR Multipliers; Multivariate Case).

1. Generate bootstrap data $\{Z_1^*, \dots, Z_T^*, Z_{T+1}^*, \dots, Z_{T+H}^*\}$ from $\widehat{\mathbb{P}}_T$.
2. Not making use of the stretch $\{Z_{H+1}^*, \dots, Z_{T+H}^*\}$, compute forecasts $\widehat{y}_T^*(h)$ and prediction standard errors $\widehat{\sigma}_T^*(h)$.
3. Identical to Algorithm 3.1.

7. Identical to Algorithm 3.1.

3.3 Comparison with Two Previous Methods

Jordà and Marcellino (2010) propose an ‘asymptotic’ method to construct a joint prediction region for $Y_{T,H}$ that controls the FWE.³ It is based on the assumption that

$$\sqrt{T}(\widehat{Y}_T(H) - Y_{T,H}|Z_T, Z_{T-1}, \dots) \xrightarrow{d} N(\mathbf{0}, \Xi_H), \quad (3.9)$$

where \xrightarrow{d} denotes convergence in distribution, and on the availability of a consistent estimator $\widehat{\Xi}_H \xrightarrow{\mathbb{P}} \Xi_H$, where $\xrightarrow{\mathbb{P}}$ denotes convergence in probability.

³They use the term *joint confidence region* instead of *joint prediction region*.

The proposed joint prediction region is given by

$$\widehat{Y}_T(H) \pm P \left[\sqrt{\frac{\chi_{h,1-\alpha}^2}{h}} \right]_{h=1}^H, \quad (3.10)$$

where P is the lower-triangular Cholesky decomposition of $\widehat{\Xi}_H/T$, satisfying $PP' = \widehat{\Xi}_H/T$, and the quantity to the right of P is a $H \times 1$ vector whose h th entry is given by $\sqrt{\chi_{h,1-\alpha}^2/h}$. This approach is problematic for several reasons.

First, assumption (3.9) implies that the conditional distribution of the vector of prediction errors $\widehat{U}_T(H) := \widehat{Y}_T(H) - Y_{T,H}$ is approximately multivariate normal with mean zero, at least for large T . This is unrealistic. The conditional distribution of a prediction error depends on the conditional distribution of the random variable to be predicted. If the latter distribution is non-normal, which is the case in many applications, then the former distribution is generally non-normal as well.

Second, assumption (3.9) implies in addition that the vector of prediction errors $\widehat{U}_T(H) := \widehat{Y}_T(H) - Y_{T,H}$ converges to zero in probability. This is unrealistic. Although, under mild regularity conditions, the difference between an estimator and the population parameter it estimates converges to zero (that is, the estimator is consistent), the same is not true for a vector of prediction errors. Even if all model parameters are known, a future observation cannot be predicted perfectly because of its random nature.

Remark 3.2. To illustrate the first two points, consider the simple AR(1) model

$$y_t = \nu + \rho y_{t-1} + \epsilon_t, \quad (3.11)$$

where $|\rho| < 1$ and the errors $\{\epsilon_t\}$ are independent and identically distributed (i.i.d.) with mean zero and finite variance $\sigma_\epsilon^2 > 0$. At time T , the forecast of y_{T+1} is given by

$$\widehat{y}_T(1) := \widehat{\nu} + \widehat{\rho} y_T, \quad (3.12)$$

where $\widehat{\nu}$ and $\widehat{\rho}$ are suitable, consistent estimators of ν and ρ . The forecast error is given by

$$\widehat{u}_T(1) = \widehat{\nu} + \widehat{\rho} y_T - y_{T+1}. \quad (3.13)$$

As T tends to infinity, the conditional distribution of $\widehat{u}_T(1)$ converges weakly to the unconditional distribution of $-\epsilon_{T+1}$ (which does not depend on T). This distribution is neither necessarily normal nor is it a point mass at zero. As a result, assumption (3.9) does not hold in this simple example. ■

Third, [Jordà and Marcellino \(2010\)](#) initially consider the following rectangular joint prediction region:

$$\widehat{Y}_T(H) \pm P \left[\sqrt{\frac{\chi_{H,1-\alpha}^2}{H}} \cdot \mathbf{1}_H \right], \quad (3.14)$$

where $\mathbf{1}_H$ is a $H \times 1$ vector of ones. It is derived by an application of Bowden's (1970) lemma to an elliptical joint prediction region based on Scheffé's (1953, 1959) method:

$$\{\tilde{Y} : T(\hat{Y}_T(H) - \tilde{Y})' \hat{\Xi}_H^{-1} (\hat{Y}_T(H) - \tilde{Y}) \leq \chi_{H,1-\alpha}^2\} . \quad (3.15)$$

As we have explained above, deriving a rectangular joint confidence region from an initial joint confidence region of elliptical form is suboptimal in terms of the volume of the rectangular joint confidence region. Furthermore, it would appear that the application of Bowden's (1970) lemma is incorrect. For the special case when Ξ_H is a multiple of the H -dimensional identity matrix, it can be seen that a projection of the elliptical region (3.15) on the axes yields the rectangular region

$$\hat{Y}_T(H) \pm P \left[\sqrt{\chi_{H,1-\alpha}^2} \cdot \mathbf{1}_H \right] , \quad (3.16)$$

so that the division of $\chi_{H,1-\alpha}^2$ by H in the region (3.14) is erroneous; for example, see Figure 1.

Fourth, [Jordà and Marcellino \(2010\)](#) arrive at their final joint prediction region (3.10) by 'refining' the initial joint prediction region (3.14) by a step-down recursive procedure that is heuristic and lacks a theoretical justification.

Fifth, a counter-intuitive feature of the joint prediction region (3.10) is that its width is not necessarily (weakly) monotonically increasing in the forecast horizon h ; for an example, see Subsection 5.1. The reason is that the multipliers $\sqrt{\chi_{h,1-\alpha}^2}/h$ can be strictly monotonically decreasing in h , at least for commonly used values of α , as illustrated in Figure 2.

Figure 2: Plot of the [Jordà and Marcellino \(2010\)](#) multipliers $\sqrt{\chi_{h,1-\alpha}^2}/h$ used in their Scheffé joint prediction region (3.10), for $H = 12$ and $\alpha = 0.1$.

Sixth, [Staszewska-Bystrova \(2012\)](#) shows that if the matrix P contains negative entries, it must be replaced by $|P|$ in the various joint prediction regions studied in [Jordà and Marcellino](#)

(2010), and in particular in their final proposal, namely in the region (3.10). In Monte Carlo simulations, we will therefore consider the *modified* Scheffé joint prediction region, given by

$$\widehat{Y}_T(H) \pm |P| \left[\sqrt{\frac{\chi_{h,1-\alpha}^2}{h}} \right]_{h=1}^H. \quad (3.17)$$

Staszewska-Bystrova (2011) proposes an alternative bootstrap method to construct a joint prediction region for $Y_{T,H}$ that controls the FWE. In a nutshell, the method works as follows. Conditional on the observed data, one generates B bootstrap path forecasts $\widehat{Y}_T^{*,b}(H)$, for $b = 1, \dots, B$. One then discards αB of these bootstrap path forecasts: namely those $\widehat{Y}_T^{*,b}(H)$ that are ‘furthest’ away from the original path forecast $\widehat{Y}_T(H)$, where the distance between two $H \times 1$ vectors is measured by the Euclidian distance.⁴ Finally, the joint prediction region is defined as the envelope of the remaining $(1 - \alpha)B$ bootstrap path forecasts, where the term *envelope* refers to the smallest region containing all remaining bootstrap path forecasts. Although this *neighboring paths (NP)* method seems to perform quite well in simulation studies, there are several concerns.

First, the method is heuristic. No proof of asymptotic validity, under some suitable high-level assumption, is provided.

Second, the method seems restricted to (vector) AR models, since it uses the backward representation of a (vector) AR model to generate the bootstrap path forecasts; see Thombs and Schucany (1990) for an early use of this representation in AR models. As an additional restriction, a problem of the backward representation when the forward errors are non-normal, is that even if the forward errors are independent, the backward errors are not independent, but merely uncorrelated; Pascual et al. (2001) point this out already. Hence, using Efron’s (1979) bootstrap on the residuals in the backward representation, as proposed by Staszewska-Bystrova (2011), may not be generally valid.

Third, the method is in the spirit of Efron’s (1979) percentile method, which amounts to “looking up the wrong tails of a distribution”; see Hall (1992, Sections 1.3 and 3.4) for a discussion. Theoretical arguments suggest that such a method can only work well when the conditional distribution of the vector of forecast errors is symmetric around zero, as would be the case for a multivariate normal distribution. The performance of the method may suffer when prediction errors are, conditionally, skewed or have non-zero mean. Staszewska-Bystrova (2011) only considers normal errors with mean zero in the data generating processes (DGPs) of her simulation study. On the other hand, the joint prediction regions we propose in Subsections 3.1 and 3.2 are based on Hall’s percentile- t method, which has a sound theoretical foundation and is more generally valid than Efron’s percentile method; again see Hall (1992, Sections 1.3 and 3.4).

Fourth, since the joint prediction region is given by the envelope of the $(1 - \alpha)B$ not-discarded bootstrap path forecasts $\widehat{Y}_T^{*,b}(H)$, the region typically has a jagged shape, which is

⁴Staszewska-Bystrova (2011) also considers other distance measures, but concludes that the Euclidean distance seems to work best.

unattractive; for an example, see Subsection 5.1.

Last but not least, it is not clear whether the methods of [Jordà and Marcellino \(2010\)](#) and [Staszewska-Bystrova \(2011\)](#) can be generalized to construct a joint prediction region for $Y_{T,H}$ that controls the k -FWE for $k \geq 2$; see (2.6). By offering a method to construct rectangular joint prediction regions for $Y_{T,H}$ that control the k -FWE for arbitrary $k \geq 1$, we provide applied researchers with a more flexible and versatile tool.

Remark 3.3 (Property of Balance). Under a mild additional assumption not covered by Assumption 3.1, our bootstrap joint prediction regions (3.2)–(3.4) can be easily seen to have the desirable property of being *balanced*, at least asymptotically.

A rectangular joint prediction region for the future path $Y_{T,H}$ is *balanced* if the probability that y_{T+h} will be contained in its implied (simultaneous) prediction interval is the same for all $h = 1, \dots, H$.⁵

To be specific, focus on the joint prediction region (3.2) whose implied prediction interval for y_{T+h} is given by $[\hat{y}_T(h) \pm d_{|\cdot|, 1-\alpha}^{k-\max, *} \cdot \hat{\sigma}_T(h)]$. Then the probability

$$\mathbb{P}\left\{y_{T+h} \in [\hat{y}_T(h) \pm d_{|\cdot|, 1-\alpha}^{k-\max, *} \cdot \hat{\sigma}_T(h)]\right\} \quad (3.18)$$

is the same for all $h = 1, \dots, H$, asymptotically, under the additional assumption that the marginal distribution of

$$\frac{\hat{y}_T(h) - y_{T+h}}{\hat{\sigma}_T(h)} \quad (3.19)$$

is the same for all $h = 1, \dots, H$, asymptotically. For example, this additional assumption holds if the time series $\{y_1, \dots, y_T, y_{T+1}, \dots, y_{T+H}\}$ is generated by an ARIMA model with i.i.d. errors, for any reasonable model-based way to compute the forecasts $\hat{y}_T(h)$ and the prediction standard errors $\hat{\sigma}_T(h)$.

A joint prediction region that is balanced implicitly treats all forecasts $\hat{y}_T(h)$ as equally important, since the probability that the k -FWE criterion will be violated is evenly spread out over all forecast horizons h .

Another way to argue that balance is a desirable property is to consider the following (extremely) unbalanced joint prediction region for $Y_{T,H}$:

$$\text{PI}_T(1) \times (-\infty, \infty) \times \dots \times (-\infty, \infty), \quad (3.20)$$

where $\text{PI}_T(1)$ is a marginal prediction interval for y_{T+1} with level $1 - \alpha$. Although this joint prediction region is clearly perverse, it nevertheless has the property of containing the entire future path $Y_{T,H}$ with the desired probability $1 - \alpha$, asymptotically (as long as the prediction interval $\text{PI}_T(1)$ has the property of containing y_{T+1} with probability $1 - \alpha$, asymptotically).

It is not clear whether the property of balance can be established for the joint prediction regions proposed by [Jordà and Marcellino \(2010\)](#) and [Staszewska-Bystrova \(2011\)](#). ■

⁵For a discussion of the concept of balance in the alternative contexts of joint confidence regions and multiple testing, the reader is referred to [Beran \(1988a,b\)](#) and [Romano and Wolf \(2010\)](#).

4 Monte Carlo Simulations

This section compares the finite-sample performance of various methods to construct joint prediction regions. We restrict ourselves to univariate forecast procedures. To this end, we use AR(p) models with various lag lengths p that are first assumed to be known. Later this assumption is relaxed and p is chosen in a data-dependent fashion. Importantly, we also generate data from non-AR(p) models, thereby allowing for model misspecification, which is very relevant to practical work.

Before we present the details of the Monte Carlo setup, we need to be specific about how we estimate the model, compute the prediction standard errors, and generate the bootstrap data in the calculation of our bootstrap joint prediction regions.

4.1 Preliminaries

The general AR(p) model is given by

$$y_t = \nu + \rho_1 y_{t-1} + \dots + \rho_p y_{t-p} + \epsilon_t, \quad (4.1)$$

where the errors $\{\epsilon_t\}$ are i.i.d. with mean zero and finite variance σ_ϵ^2 . It can be alternatively expressed as

$$y_t = \nu + \rho y_{t-1} + \psi_1 \Delta y_{t-1} + \dots + \psi_{p-1} \Delta y_{t-p+1} + \epsilon_t, \quad (4.2)$$

to bring out the role of the largest autoregressive root $\rho := \rho_1 + \dots + \rho_p$. Here, Δ is the first-difference operator, that is, $\Delta y_t := y_t - y_{t-1}$. The parameters of formulations (4.1) and (4.2) are related by

$$\rho_1 = \rho + \psi_1, \quad \rho_j = -\psi_{j-1} + \psi_j \quad \text{for } 2 \leq j \leq p-1, \quad \rho_p = -\psi_{p-1}. \quad (4.3)$$

The usefulness of bias-corrected estimators when making forecasts based on AR(p) models has been long recognized and goes back to Kilian (1998).⁶

Let $\hat{\rho}_{OLS}$ denote the usual OLS estimator of ρ based on formulation (4.2). We employ the following bias-corrected estimator of ρ .

$$\hat{\rho}_{BC} := \hat{\rho}_{OLS} + \frac{1 + 3\hat{\rho}_{OLS}}{T}; \quad (4.4)$$

for example, see White (1961). The corresponding bias-corrected estimators of $(\nu, \psi_1, \dots, \psi_{p-1})$ are obtained by regressing $y_t - \hat{\rho}_{BC} y_{t-1}$ on $(1, \Delta y_{t-1}, \dots, \Delta y_{t-p-1})$ via OLS. By relation (4.3), we obtain in turn the bias-corrected estimators of formulation (4.1), denoted by $(\hat{\nu}_{BC}, \hat{\rho}_{1,BC}, \dots, \hat{\rho}_{p,BC})$.⁷

⁶Kilian (1998) considers the construction of confidence intervals for impulse response functions, not the construction of prediction intervals for future observations. But his bias correction has since been successfully applied to the latter problem as well; for example, see Clements and Taylor (2001).

⁷Of course, other bias corrections can be employed as well, such as the bootstrap bias correction of Kilian (1998) or the analytic bias correction of Roy and Fuller (2001), though the reader is referred to <http://www.math.umbc.edu/~anindya/errata.pdf> for an errata concerning the latter reference.

The corresponding, centered residuals $\widehat{\epsilon}_t$, for $p + 1 \leq t \leq T$, are obtained as follows.

$$\widehat{\epsilon}_t := \widehat{\epsilon}_{t,BC} - \frac{1}{T-p} \sum_{l=p+1}^T \widehat{\epsilon}_{l,BC} \quad \text{with} \quad \widehat{\epsilon}_{t,BC} := y_t - \widehat{\nu}_{BC} - \widehat{\rho}_{1,BC} \cdot y_{t-1} - \dots - \widehat{\rho}_{p,BC} \cdot y_{t-p}. \quad (4.5)$$

The residual variance is

$$\widehat{\sigma}_\epsilon^2 := \frac{1}{T-2p-1} \sum_{t=p+1}^T \widehat{\epsilon}_t^2, \quad (4.6)$$

where the number of estimated parameters, $p + 1$, is subtracted from the ‘sample size’ of the residuals, $T - p$, in the numerator in the spirit of the usual definition of the residual variance in a linear regression model.

The forecasts $\widehat{y}_T(h)$ are computed in the usual fashion.

The prediction standard errors $\widehat{\sigma}_T(h)$ are computed in the usual Box-Jenkins fashion. To this end, consider the MA(∞) representation that is equivalent to the AR(p) model with parameters $(\widehat{\nu}_{BC}, \widehat{\rho}_{1,BC}, \dots, \widehat{\rho}_{p,BC})$, and denote the parameters of this MA(∞) model by $(\widehat{\theta}_0, \widehat{\theta}_1, \widehat{\theta}_2, \dots)$, with $\widehat{\theta}_0 := 1$. Then compute

$$\widehat{\sigma}_T(h) := \widehat{\sigma}_\epsilon \sqrt{\widehat{\theta}_0^2 + \dots + \widehat{\theta}_{h-1}^2}. \quad (4.7)$$

Remark 4.1. It is well known that the usual Box-Jenkins prediction standard errors (4.7) are somewhat too small in magnitude in finite samples, as they do not account for the estimation uncertainty in the model parameters $(\widehat{\theta}_0, \widehat{\theta}_1, \widehat{\theta}_2, \dots)$. However, this is not really a problem for our bootstrap approach as long as we use the same method to compute the bootstrap prediction standard errors; see Equation (4.9). Since the bias contained in the prediction standard errors is, approximately, the same in the real world compared to the bootstrap world, the resulting mistakes, approximately, cancel out and one still obtains joint prediction regions with very good finite-sample properties; see Subsection 4.3. ■

Bootstrap data $\{y_1^*, \dots, y_T^*, y_{T+1}^*, \dots, y_{T+H}^*\}$ are generated according to Pascual et al. (2001) as follows.

First, draw $\epsilon_{p+1}^*, \dots, \epsilon_{T+H}^*$ i.i.d. from the empirical distribution of $\widehat{\epsilon}_{p+1}, \dots, \widehat{\epsilon}_T$.

Second, let $y_t^* := y_t$, for $1 \leq t \leq p$ and then

$$y_t^* := \widehat{\nu}_{BC} + \widehat{\rho}_{1,BC} \cdot y_{t-1}^* + \dots + \widehat{\rho}_{p,BC} \cdot y_{t-p}^* + \epsilon_t^*, \quad \text{for } p + 1 \leq t \leq T. \quad (4.8)$$

Third, generate y_t^* , for $T+1 \leq t \leq T+H$, similarly to (4.8), but conditional on $\{y_{t-p+1}, \dots, y_T\}$ rather than on $\{y_{t-p+1}^*, \dots, y_T^*\}$.

An implication of the method of Pascual et al. (2001) is that the stretch $\{y_{T+1}^*, \dots, y_{T+H}^*\}$ is not a continuation of the stretch $\{y_1^*, \dots, y_T^*\}$. This feature appears counter intuitive at first, but it allows for bootstrap forecasts conditional on the (relevant) past of the original data rather than on the (relevant) past of the bootstrap data, which is clearly desirable.

Remark 4.2. [Thombs and Schucany \(1990\)](#) propose an alternative method to generate bootstrap data $\{y_1^*, \dots, y_T^*, y_{T+1}^*, \dots, y_{T+H}^*\}$, based on the backward representation of an $\text{AR}(p)$ model. Their method ensures that $y_t^* = y_t$, for $t - p + 1 \leq t \leq p$, so that the stretch $\{y_{T+1}^*, \dots, y_{T+H}^*\}$ is also a continuation of the stretch $\{y_1^*, \dots, y_T^*\}$. However, it only applies to $\text{AR}(p)$ models with normal forward errors ϵ_t . The method of [Pascual et al. \(2001\)](#) applies much more widely; in particular to $\text{AR}(p)$ models with possibly non-normal forward errors ϵ_t . Since the assumption of normal forward errors ϵ_t is often violated in practice, we opt for the method of [Pascual et al. \(2001\)](#). ■

Denote the bias-corrected estimators of $(\nu, \rho_1, \dots, \rho_p)$ computed from the stretch $\{y_1^*, \dots, y_T^*\}$ by $(\widehat{\nu}^*, \widehat{\rho}_{1,BC}^*, \dots, \widehat{\rho}_{p,BC}^*)$.

The bootstrap residual variance $\widehat{\sigma}_\epsilon^{2,*}$ is computed similarly to (4.6).

The bootstrap forecasts $\widehat{y}_T^*(h)$ are computed conditional on $\{y_{t-p+1}, \dots, y_T\}$ rather than on $\{y_{t-p+1}^*, \dots, y_T^*\}$.

The bootstrap prediction standard errors $\widehat{\sigma}_T^*(h)$ are computed in the same way as the ‘original’ prediction standard errors $\widehat{\sigma}_T(h)$. To this end, consider the $\text{MA}(\infty)$ representation that is equivalent to the $\text{AR}(p)$ model with parameters $(\widehat{\nu}_{BC}^*, \widehat{\rho}_{1,BC}^*, \dots, \widehat{\rho}_{p,BC}^*)$, and denote the parameters of this $\text{MA}(\infty)$ model by $(\widehat{\theta}_0^*, \widehat{\theta}_1^*, \widehat{\theta}_2^*, \dots)$, with $\widehat{\theta}_0^* := 1$. Then compute

$$\widehat{\sigma}_T^*(h) := \widehat{\sigma}_\epsilon^* \sqrt{(\widehat{\theta}_0^*)^2 + \dots + (\widehat{\theta}_{h-1}^*)^2}. \quad (4.9)$$

4.2 Monte Carlo Design

First, we consider an $\text{AR}(1)$ model with $\nu = 0$ and with $\rho := \rho_1 \in \{0.9, 0.5, -0.5, -0.9\}$. The order $p = 1$ is assumed to be known. The sample size is $T \in \{100, 400\}$. The errors ϵ_t are i.i.d. according to one of the following three distributions.

- $(\epsilon_t \sim \mathcal{N}(\mathbf{0}, 1))$ Standard normal.
- $(\epsilon_t \sim t_3)$ A t -distribution with 3 degrees of freedom, standardized to have variance one.
- $(\epsilon_t \sim \chi_3^2)$ A chi-square distribution with 3 degrees of freedom, centered to have mean zero and standardized to have variance one.

Second, we consider an $\text{AR}(2)$ model with $\nu = 0$ and $(\rho_1, \rho_2) \in \{(1.85, -0.75), (1.25, -0.75), (-0.65, 0.15), (-0.7, -0.2)\}$. The order $p = 2$ is assumed to be known. The sample size is $T \in \{100, 400\}$. The errors ϵ_t are i.i.d. according to one of the above three distributions.

Third, we consider an $\text{AR}(2)$ model with $\nu = 0$ and $(\rho_1, \rho_2) \in \{(1.85, -0.75), (1.25, -0.75), (-0.65, 0.15), (-0.7, -0.2)\}$. The order $p = 2$ is assumed to be unknown and is estimated from the data using the Bayesian information criterion (BIC) optimizing over the set $\{1, 2, \dots, 9, 10\}$.⁸

⁸The BIC is known to be a consistent information criterion, unlike the Akaike information criterion (AIC), say. Therefore, in terms of Assumption 3.1, using the BIC to estimate the order of an $\text{AR}(p)$ model is asymptotically equally valid as using the true order.

This is the case both in the ‘real’ world and in the bootstrap world.⁹ The sample size is $T \in \{100, 400\}$. For compactness, we only consider errors ϵ_t that are i.i.d. standard normal.

Fourth, we consider an MA(1) model

$$y_t = \mu + \epsilon_t + \theta\epsilon_{t-1}, \quad (4.10)$$

with $\mu = 0$ and $\theta \in \{0.9, -0.5, 0.5, 0.9\}$. For compactness, we only consider errors ϵ_t that are i.i.d. standard normal.

Fifth, we consider the nonlinear TAR model used by [Montgomery et al. \(1998, Section 2.3\)](#) in modeling the U.S. unemployment rate. This model is given by

$$y_t = \begin{cases} 0.01 + 0.73 y_{t-1} + 0.10 y_{t-2} + 0.28 \epsilon_t & \text{if } y_{t-2} \leq 0.1 \\ 0.18 + 0.80 y_{t-1} - 0.56 y_{t-2} + 0.41 \epsilon_t & \text{otherwise} \end{cases}, \quad (4.11)$$

where the errors ϵ_t are white noise with mean zero and variance one. For compactness, we only consider errors ϵ_t that are i.i.d. standard normal.

Importantly, in the last two cases, we employ the same methodology to compute joint prediction regions as in the third case: based on an AR(p) model with the lag order estimated using the BIC. Therefore, the model to compute joint prediction regions is actually misspecified, which happens often in applied work.

The following four methods to construct joint prediction regions are compared.

- **(Joint Marginals)** String together H marginal, two-sided symmetric bootstrap prediction intervals for y_{T+h} , each with nominal coverage level $1 - \alpha$.
- **(Scheffé)** The modified ‘asymptotic’ Scheffé JPR (3.17) of [Jordà and Marcellino \(2010\)](#), employing the absolute-value correction of [Staszewska-Bystrova \(2012\)](#).
- **(NP Heuristic)** The neighboring-paths heuristic bootstrap JPR of [Staszewska-Bystrova \(2011\)](#).
- **(k -FWE JPR)** Our two-sided bootstrap JPR (3.2).

The nominal k -FWE level is $\alpha = 0.1$. We consider $k \in \{1, 2, 3\}$ for k -FWE JPR. All other methods only use $k = 1$. The forecast horizon is $H \in \{6, 12, 24\}$. The number of bootstrap samples for k -FWE JPR and NP Heuristic is $B = 1,000$ always.

All empirical coverages are computed from 1,000 generated data sets $\{y_1, \dots, y_T\}$, each with 100 corresponding, independent continuations $\{y_{T+1}, \dots, y_{T+H}\}$. As a result, the empirical coverages are based on a total of 100,000 repetitions each, and are thus highly accurate. For each scenario, we report the proportion of times that the k -FWE criterion is not violated. The thus-obtained empirical coverages should be compared to the nominal coverage level given by $1 - 0.1 = 0.9 = 90\%$.

For the cases where the lag order p is estimated using the BIC, which are the most relevant cases for applied work, we also compute empirical geometric-average widths of the various JPRs to compare their ‘sizes’ or ‘volumes’. More specifically, any rectangular JPR is the

⁹As a result, it is possible that a different order is used in the ‘real’ world compared to the bootstrap world.

cartesian product of H simultaneous prediction intervals $\text{PI}_1, \dots, \text{PI}_H$, with corresponding widths w_1, \dots, w_H . The geometric average of the H widths is given by

$$\bar{w}_{\text{geo}} := (\prod_{h=1}^H w_h)^{1/H},$$

and is a one-to-one function of the volume of the joint prediction region, $\prod_{i=1}^H w_i$. (The reason that we record the geometric average instead is that this makes it easier to study a ‘typical’ width as we increase H , keeping everything else the same.) For a given scenario, we report the sample mean of the \bar{w}_{geo} over all 1,000 simulations as the empirical geometric-average width.

4.3 Results

The results for the AR(1) model with $p = 1$ known are presented in Tables 1–2. The results for the AR(2) model with $p = 2$ known are presented in Tables 3–4. The results for the AR(2) model with $p = 2$ unknown and estimated using the BIC are presented in Tables 5–6. The results for the MA(1) model are presented in Tables 7–8. Finally, the results for the TAR model are presented in Tables 9–10.

The various results concerning empirical coverage can be summarized as follows.

- Joint Marginals always undercovers and its performance gets worse as the maximum forecast horizon H increases. This behavior is as expected and has been demonstrated before by [Jordà and Marcellino \(2010\)](#) and [Staszewska-Bystrova \(2011\)](#) already. Nevertheless, it is worth repeating the underlying message one more time: stringing together marginal prediction intervals does not result in a valid joint prediction region for the entire future path.
- The performance of Scheffé ranges from acceptable to poor. In general, the performance decreases in the maximum forecast horizon H . For many scenarios, the empirical coverage is unacceptably far away from the nominal level and can even fall below 50%. As a consequence, Scheffé cannot be recommended for practical application. It should be pointed out that the original Scheffé method (3.10), without the absolute-value correction of [Staszewska-Bystrova \(2012\)](#), performs even worse and can have coverage probability near zero when the matrix P contains negative entries.¹⁰
- The performance of NP Heuristic is good when the largest autoregressive root is close to one. Otherwise, the performance is acceptable: the empirical coverage generally is somewhat less than the nominal level and decreases in the maximum forecast horizon H , even for $T = 400$.
- The performance of k -FWE JPR is the best of all methods; it ranges from very good to good. There can be some mild undercoverage when $T = 100$ and $H = 24$; but in almost all cases, the empirical coverage is very close to the nominal level. In particular, the performance is remarkably stable, both over the maximum forecast horizon H and over the value of k in the k -FWE criterion.

¹⁰Corresponding results are available from the authors upon request.

- When the distribution of the errors is heavy tailed or skewed, as opposed to normal, the performance of all methods generally suffers somewhat. However, it suffers less for k -FWE JPR compared to NP Heuristic, which is the only competitor with acceptable coverage properties.
- There is no noticeable penalty to not knowing the AR model order p . When p is estimated from the data using the BIC, the empirical coverages are generally close to the corresponding coverages for known p , even for $T = 100$ already.
- When the $AR(p)$ forecasting model is misspecified, the ranking of the various methods remains unchanged. Furthermore, k -FWE JPR is more robust to model misspecification than NP Heuristic. This is an important finding for applied researchers: k -FWE JPR based on the $AR(p)$ forecasting model has the potential to work well for general stationary time series, even for nonlinear ones.

The various results concerning empirical geometric-average widths can be summarized as follows.

- As expected, Joint Marginals has the smallest geometric-average width throughout.
- Despite its poor coverage properties, Scheffé has larger geometric-average width than NP Heuristic or 1-FWE JPR in some scenarios.
- NP Heuristic has generally somewhat smaller geometric-average width than 1-FWE JPR, which is perfectly in line with its generally somewhat smaller coverage probabilities. In other words, adjusted for coverage, there does not appear any noticeable difference in geometric-average width between the two methods.
- As expected, the geometric-average width of k -FWE JPR decreases in k and the differences are quite large. As a result, there really is a payoff in terms of ‘volume’ of the JPR if the applied researcher is willing to choose a value of k larger than one.

Figure 3: Quarterly data on US real gross domestic product (in 2005 chained dollars) from Q1/1947 until Q3/2001. The upper panel displays the raw data and the lower panel displays the first differences of the logarithmic data (in percent).

5 Empirical Application

The goal of this section is to compare the various joint prediction regions for a set of real data. To this end, we downloaded quarterly data on US real gross domestic product from Q1/1947 until Q3/2011, made freely available by the Federal Reserve Bank of St. Louis.¹¹ The data are seasonally adjusted and expressed in billions of chained 2005 dollars. Figure 3 displays the raw data as well as the first differences of the logarithmic data (in percent). We take the latter series as our series of interest with a total of 258 observations. The task then is to forecast log quarter-to-quarter growth for the next H quarters and to compute corresponding joint prediction regions. We choose $H = 12$, which corresponds to a maximum forecast horizon of three years. The nominal coverage is given by $1 - \alpha = 90\%$.

¹¹The data can be downloaded at <http://research.stlouisfed.org/fred2/series/GDPC1/>.

We use the AR(p) methodology described in Section 4 to compute bootstrap joint prediction regions, where the lag order p is assumed to be unknown and estimated from the (bootstrap) data using the BIC. Of course, a more ‘complex’ methodology could be used instead, such as a multivariate forecasting model based on additional macroeconomic variables (for example, see [Stock and Watson, 2001](#)) or a nonlinear forecasting model (for example, see [Potter, 1995](#)). The goal of this section, however, is not necessarily to find the single best forecasting model for the given data set but to see how the various joint prediction regions behave relative to each other for a common, simple and reasonable forecasting model, such as the AR(p) model.

5.1 Illustration Exercise

We first illustrate the salient features of the various joint prediction regions by using the last $T = 120$ quarters (or 30 years) to forecast the not-yet observed future path ranging from Q4/2011 until Q3/2014. We do not use the entire data set, since the assumption of stationarity is doubtful, given that the overall volatility seems to have decreased after 1980.

The lag order for the original data estimated by the BIC is $\hat{p} = 1$. The initial model fitted via OLS is given by

$$\hat{y}_{t+1} = 0.318 + 0.542 \cdot y_t . \quad (5.1)$$

Using the bias correction (4.4) yields the following final model used for forecasting purposes:

$$\hat{y}_{t+1} = 0.304 + 0.564 \cdot y_t . \quad (5.2)$$

Figure 4 compares Scheffé, NP-Heuristic, and 1-FWE JPR.¹² The main findings are as follows:

- Scheffé has a substantially smaller volume than the other two regions: this is not surprising given the simulation results of the previous section, where it was seen that Scheffé typically undercovers by a substantial amount.
- A further, counter-intuitive feature of Scheffé is that its width is non-monotonic in the forecasting horizon h : the width is largest for $h = 7$ and monotonically decreases after that, if only slightly. The theoretical reason for this counter-intuitive feature was discussed in Subsection 3.3.
- Although NP Heuristic and 1-FWE JPR are comparable in terms of their volume, an unattractive feature of NP Heuristic is its jagged shape, which is a result of the underlying methodology; see Subsection 3.3.

Figure 5 compares 1-FWE JPR, 2-FWE JPR, and 3-FWE JPR. As implied by theory, the volume of k -FWE JPR decreases in the value of k . Therefore, if the applied researcher is willing to miss up to one (or two) elements of the future path in the joint prediction region (with prespecified probability 90%), he obtains a smaller and more informative region in return.

¹²The number of bootstrap samples for NP-Heuristic and k -FWE JPR is $B = 10,000$.

Figure 4: path forecast and various joint prediction regions for US log real GDP growth. The forecast period ranges from Q4/2011 until Q3/2014. The nominal coverage is given by $1 - \alpha = 90\%$.

Figure 5: path forecast and various joint prediction regions for US log real GDP growth. The forecast period ranges from Q4/2011 until Q3/2014. The nominal coverage is given by $1 - \alpha = 90\%$.

5.2 Backtest Exercise

Although the previous exercise serves to illustrate the salient features of the various joint prediction regions, it does not address their performance in terms of coverage. First, the data ranging from Q4/2011 until Q3/2014 have not been entirely observed yet (at the time of writing this paper). Second, even when these data become eventually known, they only correspond to a single instance of a path; to compute meaningful empirical coverages a large number of such paths are needed.

Therefore, we resort to the following backtest exercise, for a given method to construct a joint prediction region (JPR) designed to control the k -FWE:

- Using the stretch $\{y_t, \dots, y_{t+119}\}$ only, compute the JPR for the next $H = 12$ periods.
- Compare the computed JPR against the path $(y_{t+120}, \dots, y_{t+131})'$ to check whether all but at most $k - 1$ elements of the path are contained in the JPR. If the answer is yes, call the outcome a ‘success’.
- Do this for $t = 1, \dots, 258 - 120 - 12 = 126$.
- Report the empirical coverage as the fraction of ‘successes’ out of these 126 ‘trials’.

This means that we use a rolling window of 120 quarters to compute a JPR for the next path of $H = 12$ quarters. Since only ‘past and present’ information is used to forecast the ‘future’, we get a fair assessment of a method’s out-of-sample performance in this way. Although the assessment is fair, it is not overly accurate, since the empirical coverage is based on 126 out-of-sample ‘trials’ only, which are not even independent of each other.

The results are presented in Table 11.¹³ It is seen that Joint Marginals and Scheffé under-cover by a substantial amount while NP Heuristic and k -FWE JPR perform very well to well. These findings are line with those of the Monte Carlo simulations of the previous section.

Nominal Coverage $1 - \alpha = 90\%$	
Method	Empirical Coverage
Joint Marginals	64.5
Scheffé	83.4
NP Heuristic	87.7
1-FWE JPR	89.9
2-FWE JPR	85.1
3-FWE JPR	87.3

Table 11: Empirical Out-Of-Sample Coverages for US Log Real GDP Growth.

¹³The number of bootstrap samples for NP-Heuristic and k -FWE JPR is $B = 5,000$.

6 Concluding Remarks

Many statistical applications require the forecast of a random variable of interest over several periods into the future, that is, one needs to forecast an entire future path. In addition to the resulting path forecast, one often would also like to compute a corresponding joint prediction region. Such a region is supposed to contain the entire future path with a prespecified probability $1 - \alpha$.

In this paper, we have proposed bootstrap joint prediction regions of three different shapes: one-sided lower, one-sided upper, and two-sided. This way, the applied researcher can choose the most suitable shape for the task at hand. Furthermore, the joint prediction regions are completely generic in that they allow the applied researcher to select whichever methods are deemed most appropriate by him to make forecasts, compute prediction standard errors, and generate bootstrap data.

Compared to two previous proposals in the literature, our bootstrap joint prediction regions have two important advantages. First, they are proven to be asymptotically consistent under a realistic, mild high-level assumption. Second, they enjoy superior finite-sample properties, as demonstrated via extensive Monte Carlo simulations.

As an additional bonus, we also offer generalized joint prediction regions obtained by the bootstrap. Such regions are not required to contain the entire future path but only the entire future path up to a small, user-defined number of elements, with prespecified probability $1 - \alpha$. If the maximum forecast horizon is large, it may be deemed acceptable by the applied researcher that a small number, such as one or two, of elements of the future path fall outside the joint prediction region. In return, he will then obtain a smaller and more informative region.
